Abstract

In mammals, germ cells within the developing gonad follow a sexually dimorphic pathway. Germ cells in the murine ovary enter meiotic prophase during embryogenesis, whereas germ cells in the embryonic testis arrest in G0 of mitotic cell cycle and do not enter meiosis until after birth. In mice, retinoic acid (RA) signaling has been implicated in controlling entry into meiosis in germ cells, as meiosis in male embryonic germ cells is blocked by the activity of a RA-catabolizing enzyme, CYP26B1. However, the mechanisms regulating mitotic arrest in male germ cells are not well understood. Cyp26b1 expression in the testes begins in somatic cells at embryonic day (E) 11.5, prior to mitotic arrest, and persists throughout fetal development. Here, we show that Sertoli cell-specific loss of CYP26B1 activity between E15.5 and E16.5, several days after germ cell sex determination, causes male germ cells to exit from G0, re-enter the mitotic cell cycle and initiate meiotic prophase. These results suggest that male germ cells retain the developmental potential to differentiate in meiosis until at least at E15.5. CYP26B1 in Sertoli cells acts as a masculinizing factor to arrest male germ cells in the G0 phase of the cell cycle and prevents them from entering meiosis, and thus is essential for the maintenance of the undifferentiated state of male germ cells during embryonic development.

Introduction

Retinoic acid (RA) is a vitamin A derived signaling molecule that regulates cell proliferation, migration, and differentiation during embryonic development and adult homeostasis. RA-mediated signaling is controlled in embryonic tissues through coordinated regulation of RA synthesis and catabolism. Synthesis is catalyzed by a family of retinaldehyde dehydrogenases (ALDH1A1, ALDH1A2 and ALDH1A3) that irreversibly oxidize retinal to form RA, while catabolism is facilitated by a family of cytochrome P450 enzymes (CYP26A1, CYP26B1 and CYP26C1), which convert RA to more polar, inactive metabolites [1,2]. Therefore, the distribution and activity of these enzymes define where RA signaling will occur. Gene targeting studies have demonstrated that changing the endogenous distribution of RA can have severe consequences for the developing embryo. Aldh1a2−/− embryos die around embryonic day (E) 10.5 and display phenotypes resembling severe maternal vitamin A deficiency, while Cyp26a1 and Cyp26b1 null embryos exhibit numerous malformations reminiscent of RA teratogenicity [3-8].

Recent genetic studies suggest that RA plays a role in the development of embryonic germ cells [9-11]. In mice, primordial germ cells (PGCs) migrate from the proximal epiblast and reach the developing gonad between E10 and 11. PGCs continue to divide mitotically for a few days and then germ cells in males and females follow a sexually dimorphic pathway. In males, in response to a hypothesized unidentified masculinizing factor, germ cells arrest in G0 phase in the mitotic cycle [12,13]. Cells re-enter the cell cycle a few days after birth, and the first meiotic spermatocytes are seen at postnatal day (P) 10 [14]. In contrast, female germ cells continue through the cell cycle to enter prophase of the first meiotic division, and progress through leptotene, zygotene and pachytene, arresting in diplotene just before birth [15]. In the embryonic male gonad, Cyp26b1 transcripts are detected in somatic cells as early as E11.5 and persist throughout development [16]. Cyp26b1 expression is detected in peritubular myoepithelial cells in the postnatal testis, while Cyp26b1 expression is absent in developing and adult ovaries [17]. Aldh1a2 expression in the gonad initiates at E10.5 in the mesonephros and is maintained until at least E13.5. Postnatally, Aldh1a2 transcripts are detected at P1, and expression increases significantly until P20 when protein is detected in pachytene spermatocytes, and later in the adult expression is restricted to round spermatids [17]. Therefore, in the male gonad, the expression of Aldh1a2 and Cyp26b1 acts as a
Sertoli cell-specific knockout mouse line of CYP26B1: regulating male germ cell development. We have generated a floxed Cyp26b1 allele. In order to detect a null allele, DNA was extracted from 223 bp from a wild-type allele and 284 bp from a targeted (L3) allele. In order to determine the mitotic index of germ cells, the total number of Ki67-stained or unstained germ cells (MVH-labeled cells) in the entire cross section was counted under a microscope. At least five cross sections were analyzed for each developmental stage.

**Materials and Methods**

**Generation and genotyping of Cyp26b1<sup>flo</sup>/<sup>flo</sup> mice**

Mice in which exons 3–6 of the Cyp26b1 locus are flanked by loxP sites have been previously described [9]. These animals (Cyp26b1<sup>flo/lo</sup>) were crossed with mice expressing Cre recombinase under the control of the anti-Müllerian hormone (Amh) promoter. As the Amh-Cre transgene is expressed only in Sertoli cells from E15 onwards [20], this conditional knockout mouse line of Cyp26b1 allows us to define the role of CYP26B1 in male germ cells after E15, when they are already committed to the male developmental pathway.

**RNA extraction and reverse transcription–polymerase chain reaction (RT-PCR)**

Total RNA was isolated from freshly dissected gonads with Trizol reagent (Invitrogen, Carlsbad, CA) according to the manufacturer’s recommendations. Total RNA (1 µg) was reverse transcribed with random hexamers (0.2 µg) using 30 units avian myeloblastosis virus reverse transcriptase (Promega Madison, WI) in a total reaction volume of 25 µL. PCR was conducted by using 1 µL of cDNA as template in a total volume of 20 µL. The following primer sets were used: Stra8: 5'-CTGTGGACCA-GAGTCTGAA-3' and 5'-GCAACGAGTGGGAGAGAGAGA-3'; and mouse vasa homolog (Mvh): 5'-TGGCAGAGCTGCTTTTT-3' and 5'-GGGTTGATACCTGCTGCT-3'.

**Tissue collection and histology**

Freshly dissected testes from Cyp26b1<sup>flo/lo</sup> and appropriate control mice were fixed for 1 h in Bouin’s solution, washed in 70% ethanol and paraffin embedded. Sections (5 µm) were cut, de waxed, and stained with hematoxylin and eosin as previously described [9]. At least four testes from mice of each genotype were examined at each developmental stage.

**Immunofluorescence**

For immunofluorescence (IF) experiments, sections were blocked in 5% serum (matched to the species of the secondary antibody) in PBS for 30 min at room temperature and then incubated with primary antibodies overnight at 4°C prior to detection with secondary antibodies. Primary antibodies used for IF were rabbit anti-mouse vasa homolog (Mvh, 1:2000, provided by T. Noce), mouse anti-Ki67 (1:400, BD Bioscience), rabbit anti-SC35 antisem (1:500, provided by C. Heyting) [21], rat anti-TRA98 (1:1000, provided by H. Tanaka and Y. Nishimune), and rabbit anti-38-hydroxysteroid dehydrogenase (38HSD) (1:500, provided by A. Payne). Secondary antibodies used were goat anti-rabbit Alexa 488, goat anti-rat Alexa 594 and goat anti-mouse Alexa 594 (1:500, Molecular Probes). Sections were counterstained with nuclear stain 4′-diamidino-2-phenylindole (DAPI). Images were obtained using a Nikon Eclipse TE 2000-U microscope. Negative controls, lacking the primary antisera, were included in each experiment.

In order to determine the mitotic index of germ cells, the total number of Ki67-stained or unstained germ cells (MVH-labeled cells) in the entire cross section was counted under a microscope. At least five cross sections were analyzed for each developmental stage.

**Results**

**Sertoli cell specific excision of Cyp26b1**

Mice in which exons 3–6 of Cyp26b1 (Cyp26b1<sup>flo/lo</sup>) are flanked by loxP sites (Figure 1A) were generated as previously described [9]. These animals were crossed with Amh-Cre mice, which express Cre recombinase specifically in Sertoli cells, known hereafter as Cyp26b1<sup>flo/lo</sup> mice (Figure 1A). In order to confirm specificity of Cre activity in Cyp26b1<sup>flo/lo</sup> mice, DNA was extracted from tails and testes of Cyp26b1<sup>flo/lo</sup> animals as well as wild-type littermates harboring the Amh-Cre transgene (Cyp26b1<sup>flo/lo</sup>). Genotyping was performed using appropriate primers, and excision of Cyp26b1 was detected only in the testes of Cyp26b1<sup>flo/lo</sup> animals (Figure 1B, 364 bp band). It should be noted in the testes of Cyp26b1<sup>flo/lo</sup> mice, a band corresponding to a floxed Cyp26b1 allele was still detected by PCR (Figure 1B, 284 bp band). This may indicate that there was not 100% excision of the Cyp26b1<sup>flo/lo</sup> locus, or may reflect amplification of DNA extracted from non-Sertoli cells in the testes.
We next sought to determine the timing of loss of CYP26B1 activity in Cyp26b1\(^{SC-/SC-}\) mice by examining the expression of 
\(Stra8\), a RA-responsive gene. \(Stra8\) expression is absent in wild type embryonic testes. In Cyp26b1\(^{+/+}\) embryonic testes, \(Stra8\) expression is induced \([10]\). RT-PCR analysis showed no \(Stra8\) expression in either Cyp26b1\(^{SC-/SC-}\) or Cyp26b1\(^{SC/-SC}\) mice at E15.5 (Figure 2), indicating that RA levels remained unchanged at E15.5. At E16.5, \(Stra8\) mRNA was detected in Cyp26b1\(^{SC/-SC}\) testes but not in Cyp26b1\(^{SC-/SC-}\) testes (Figure 2). 

Testis degeneration in Cyp26b1\(^{SC-/SC-}\) mice

Cyp26b1\(^{SC-/SC-}\) mice were healthy, viable and did not show any abnormalities of external genitalia. However, they had smaller testes than littersmates having at least one wild-type Cyp26b1 allele. Morphological evaluation of testes from 3-month-old Cyp26b1\(^{SC-/SC-}\) mice revealed an incompletely penetrant phenotype of abnormal seminiferous tubules, with some devoid of all germ cells (Figure 3A, B, asterisks) while other tubules contained cells from all stages of spermatogenesis. IF with the germ cell specific antibody TRA98, confirmed that germ cells were depleted
in some seminiferous tubules of Cyp26b1SC−/SC− animals (Figure 3C, D). Other cell types were examined using antibodies to GATA1 (Sertoli cell specific marker) and 3βHSD (Leydig cell specific marker). It was also noted that in Cyp26b1pSC−/SC− samples, the diameter of seminiferous tubules lacking germ cells was reduced, and Leydig cell hyperplasia was evident outside these tubules (Figure 3F). Such abnormalities were not observed in Cyp26b1+/+ or Cyp26b1+/− control testes (Figure 3, A, C, E, data not shown). In contrast, numbers of Sertoli cells were unchanged between mutant (Figure 3F) and control animals (Figure 3E).

Loss of gonocytes in Cyp26b1SC−/SC− neonatal testes

The observed depletion of spermatogenic cells could be due to either i) the disruption of spermatogenesis, or ii) the loss of gonocytes, which are precursor cells of spermatogenesis. In order to distinguish between these two possibilities, IF was performed on sections from Cyp26b1pSC−/SC− testes at P0 using the germ cell-specific antibody TRA98.

Overall, Cyp26b1pSC−/SC− testes contained fewer germ cells in comparison with Cyp26b1p+/+ testes (Figure 4). In contrast to Cyp26b1p+/+ testes where germ cells were present in all seminiferous tubules, (Figure 4A), some seminiferous tubules were devoid of germ cells in Cyp26b1pSC−/SC− testes (Figure 4B), indicating that there is loss of germ cells by P0.

Meiotic germ cells are detected in E16.5 Cyp26b1SC−/SC− testes

Previously, we observed that loss of CYP26B1 function by E11.5 resulted in the inappropriate initiation of meiotic prophase in testes. As Stra8 expression is not induced at E15.5 in Cyp26b1SC−/SC− mice, testes were collected and sectioned from E15.5 and E16.5 Cyp26b1SC−/SC− and control fetuses. Sections were stained for the synaptonemal complex protein SCP3, a marker indicative of meiosis, which is upregulated in Cyp26b1p−/− testes [9,10]. At E15.5, no SCP3-stained cells were seen in either Cyp26b1p+/+ or Cyp26b1pSC−/SC− testes (data not shown). At E16.5, in contrast to Cyp26b1p+/+ SCP3+ testes in which no SCP3-stained cells were observed, SCP3-positive cells were detected in a subset of tubules in Cyp26b1pSC−/SC− testes (Figure 5).

Germ cells exit from G0 and re-enter mitosis in E16.5 Cyp26b1SC−/SC− testes

In order to determine if CYP26B1 is required for maintaining mitotic quiescence in male germ cells, E15.5 and E16.5 testes were collected and IF was performed with antibody to Ki67 (Figure 6B, E, H, K), which detects all phases of the cell cycle except for G0 and is a common marker of mitotic cells. Samples were also labeled with the germ cell-specific antibody, MVH (Figure 6A, D, G, J). At E15.5, Cyp26b1p+/+ and Cyp26b1pSC−/SC− testes contained very few Ki67-positive germ cells (<1%), while somatic cells stained with Ki67 (Figure 6). At E16.5, virtually no Ki67 expressing germ cells were detected in
Cyp26b1 SC−/SC− male germ cells enter meiosis prematurely. Sections of testes from Cyp26b1 SC+/SC+ (A) and Cyp26b1 SC−/SC− (B) littermates at E16.5 stained for the meiotic marker SCP3 (green). Sections were counterstained with DAPI. Bar, 20 μm. doi:10.1371/journal.pone.0007501.g005

Cyp26b1 SC+/SC+ testes (Figure 6I), whereas 22% of the germ cells were Ki67-positive in the testes of Cyp26b1 SC−/SC− mice (Figure 6L, arrowheads). There was no significant difference in the overall number of Ki67-stained somatic cells between Cyp26b1 SC−/SC− and control mice.

Discussion

We previously reported that genetic deletion of Cyp26b1 by E11.5, prior to the germ cell sex determination, leads to increased RA levels in the embryonic testes resulting in premature meiotic initiation and apoptosis in male germ cells [9]. In the present study, we have specifically knocked out Cyp26b1 in Sertoli cells from E15.5 onwards. We observed induction of Stra8 expression and initiation of meiosis in germ cells as early as E16.5, and a loss of germ cells by P0, resulting in abnormal seminiferous tubules devoid of germ cells in adult testes. Furthermore, it was observed that some male germ cells at E16.5 exit from G0 and enter the cell cycle, a process that normally does not occur until a few days after birth. These results suggest that male germ cells retain the ability to commit to male or female development until at least E15.5. CYP26B1 in Sertoli cells during embryonic development keeps male germ cells undifferentiated by arresting them in mitotic quiescence and preventing them from meiotic entry until after birth, when mitosis resumes and meiosis initiates as required for spermatogenesis.

It has been proposed that all germ cells enter meiosis cell autonomously unless prevented from doing so by an unidentified factor.

Figure 5. Cyp26b1 SC−/SC− male germ cells enter meiosis prematurely. Sections of testes from Cyp26b1 SC+/SC+ (A) and Cyp26b1 SC−/SC− (B) littermates at E16.5 stained for the meiotic marker SCP3 (green). Sections were counterstained with DAPI. Bar, 20 μm. doi:10.1371/journal.pone.0007501.g005

CYP26B1 and Germ Cells

Figure 6. Re-entry into mitotic cell cycle in embryonic Cyp26b1 SC−/SC− male germ cells. Sections of testes from Cyp26b1 SC+/SC+ (A, B, C, G, H, I) and Cyp26b1 SC−/SC− (D, E, F, J, K, L) littermates at E15.5 (A–F) and E16.5 (G–L) stained for the mitotic marker Ki67 (B, E, H, K, red) and the germ cell marker MVH (A, D, G, J, green). Overlays of images show Ki67 expressing germ cells are observed only in Cyp26b1 SC−/SC− fetuses (F, arrowheads). Bar, 20 μm. doi:10.1371/journal.pone.0007501.g006
meiosis-preventing substance (MPS) in the embryonic testis [12]. Germ cells enter meiotic prophase during embryogenesis not only in ovaries, but also in non-gonadal regions where germ cells escape the inhibitory influence of MPS. When male germ cells from E10.5 or E11.5 gonads are cultured with disaggregated embryonic lung cells, they enter meiotic prophase, but germ cells from older male embryos (E12.5 and E13.5) do not enter meiosis [12]. Based on these observations, it has been proposed that the decision in germ cells to commit to a male or female pathway is made between E12.5 and 13.5 [12]. Previously, it was shown that in Cyp26b1SC−/SC− fetuses, male germ cells enter meiosis at E13.5 [9]. In the Cyp26b1SC−/SC− model that we have described, CYP26B1 activity is not lost until between E15.5 and E16.5, when male germ cells arrest in G0 and are normally already committed to develop along a male pathway. However, in Cyp26b1SC−/SC− fetuses, meiotic germ cells are detected at E16.5, suggesting that male germ cells at E13.5 still retain the potential to initiate meiosis and that the commitment of these cells to the male developmental pathway is reversible. These observations demonstrate that CYP26B1 functions as a MPS to prevent male germ cells from entering meiosis in various stages of development, and without its inhibitory influence, male germ cells enter meiosis even though they are already committed to the male developmental pathway. Altogether, these observations suggest that entry into meiosis is the result of an inductive program subject to RA signaling, rather than a cell-intrinsic event.

Importantly, we find that Cyp26b1SC−/SC− male germ cells exit from G0 and re-enter the mitotic cell cycle. In mice, germ cells within the developing gonad undergo sexually dimorphic cell cycles between E12.5 and E15.5. This developmental switch is dependent on the sex of the somatic cells, rather than the sex chromosome constitution of the germ cells [12]. It has been proposed that a masculinizing factor(s) produced by somatic cells direct male germ cells to arrest in G0 of the cell cycle instead of entering the meiosis as female germ cells do at the same time [12]. The finding that Cyp26b1SC−/SC− male germ cells exit from G0 and re-enter the mitotic cell cycle is significant, as it shows that CYP26B1 activity in Sertoli cells not only prevents meiosis in germ cells, but is also required for maintaining mitotic arrest in the developing testes, suggesting that CYP26B1 (due to its RA-catabolizing activity) is a candidate masculinizing factor. Furthermore, our findings demonstrate that male germ cells at E15.5 and older retain the ability to continue through the mitotic cell cycle and enter meiotic prophase in response to RA signaling. Thus, CYP26B1 activity in Sertoli cells keeps male germ cells undifferentiated during embryonic development. It has been reported that RA promotes the proliferation of both cultured PGCs [22] and embryonic male germ cells, but has no effects on the somatic cell proliferation [23]. We have provided in vivo evidence that male germ cells must remain in an RA-depleted state to enter mitotic arrest. In the mouse testes, germ cells arrest in G0 of the cell cycle between E12.5–E15.5, which coincides with the expression of Cyp26b1 in the male gonad. Germ cells remain in mitotic quiescence until shortly after birth when mitosis is resumed as required for spermatogenesis [24]. This timing corresponds with testicular expression of Aldh1a2, as ALDH1A2 is first detected in

**Figure 7. Proposed model for the role of CYP26B1 in maintaining male germ cells in an undifferentiated state during embryogenesis.** In wild-type gonads, germ cells exhibit sex-specific divergence during embryogenesis as male germ cells enter mitotic arrest, while female germ cells enter mitosis followed by meiosis. However, in Cyp26b1SC−/SC− fetuses, Cyp26b1 activity is inactivated after E15.5, thus elevating levels of retinoic acid within the testes. As a result, male germ cells exit from G0 to re-enter the cell cycle and initiate meiotic prophase, which subsequently culminates in loss of male germ cells.

doi:10.1371/journal.pone.0007501.g007
the developing testis at birth, and levels increase postnatally [17]. Collectively, these results suggest that RA signaling may also play a role in maintaining the mitotic activity in both PGCs and undifferentiated spermatogonia in postnatal tests.

In the embryonic testes, the ALDHs and CYP26B1 act as a source and sink for RA. It has been proposed that RA is synthesized in the mesonephros by ALDH1A enzymes, and diffuses into adjacent cells until reaching Sertoli cells where it is catabolized by CYP26B1. This process is essential for germ cell maturation, as an RA-depleted environment is required for the entry of male germ cells into mitotic arrest and thus prevents germ cells from entry into meiotic prophase. CYP26B1 in Sertoli cells directs male germ cells to develop along a male pathway (mitotic quiescence) and maintains the undifferentiated state of the male germ cells from E11.5 onward. However, the absence of CYP26B1 in Sertoli cells enables endogenous levels of RA to rise in the testes at a time when they should be low or absent. Subsequently, germ cells exit the G0 stage to re-enter the cell cycle and initiate meiotic prophase (Figure 7). At this point, we hypothesize that a factor is released from Sertoli cells that either directly, or indirectly initiates apoptosis of germ cells. The identity of such a factor(s), and mechanisms underlying initiation of apoptosis are currently under investigation.
