ABSTRACT

This Letter utilizes composite spectral energy distributions (SEDs) constructed from NEWFIRM Medium-Band Survey photometry to constrain the dust attenuation curve in 0.5 < z < 2.0 galaxies. Based on similarities between the full SED shapes (0.3–8 μm), we have divided galaxies in 32 different spectral classes and stacked their photometry. As each class contains galaxies over a range in redshift, the resulting rest-frame SEDs are well sampled in wavelength and show various spectral features including Hz and the UV dust bump at 2175 Å. We fit all composite SEDs with flexible stellar population synthesis models, while exploring attenuation curves with varying slopes and UV bump strengths. The Milky Way and Calzetti law provide poor fits at UV wavelengths for nearly all SEDs. Consistent with previous studies, we find that the best-fit attenuation law varies with spectral type. There is a strong correlation between the best-fit dust slope and UV bump strength, with steeper laws having stronger bumps. Moreover, the attenuation curve correlates with specific star formation rate (SFR), with more active galaxies having shallower dust curves and weaker bumps. There is also a weak correlation with inclination. The observed trends can be explained by differences in the dust-to-star geometry, a varying grain size distribution, or a combination of both. Our results have several implications for galaxy evolution studies. First, the assumption of a universal dust model leads to biases in derived galaxy properties. Second, the presence of a dust bump may result in underestimated values for the UV slope, used to correct SFRs of distant galaxies.

Key words: dust, extinction – galaxies: stellar content

Online-only material: color figures

1. INTRODUCTION

After dark matter, dust may be the most mysterious component of galaxies. Aside from the Milky Way (MW) and a few well-studied galaxies, we know little about the types of grains, the distribution of dust with respect to stars, or the dust to gas or dust to star ratio. Consequently, the dust production and destruction cycle and the role of dust within the baryon cycle of galaxies are poorly understood (e.g., Draine 2009; Matsuura et al. 2009; Gall et al. 2011). We know that dust affects the energy balance in the interstellar medium (ISM), the cooling of gas, and hence star formation. However, dust is currently not included in theoretical galaxy evolution models, and appropriate observations needed to constrain these processes are still missing. Moreover, in order to study the stellar populations of galaxies, we must have a solid understanding of the properties and spatial distribution of dust.

When deriving the properties of distant galaxies from photometric or spectroscopic observations, we commonly assume a uniform attenuation law, often implemented as a simple screen. Yet we know that the dust attenuation law is not universal. For example, the MW and the Large Magellanic Cloud (LMC) extinction curve to a lesser extent exhibit a dust absorption feature around 2175 Å (Stecher 1965), which is absent in four out of five sight-lines toward the Small Magellanic Cloud (SMC) and in an empirical attenuation curve for starburst galaxies (Calzetti et al. 2000). This feature has been seen in other galaxies as well, out to z ~ 1 or even higher, though not as strong as for the MW (e.g., Motta et al. 2002; Burgarella et al. 2005; Noll et al. 2009; Elbaz et al. 2009; Conroy et al. 2010a; Conroy 2010; Wild et al. 2011; Buat et al. 2011). The slope of the attenuation curve also varies among different sight-lines and galaxies.

Variations in the dust attenuation curve are expected on theoretical grounds (Witt & Gordon 2000). However, the origin of the observed differences between the various laws are poorly understood. For example, we do not know what types of grains are responsible for the 2175 Å dust bump (e.g., Draine & Malhotra 1993), or what physical process governs its strength. We stress that dust attenuation and extinction are distinct concepts; attenuation includes dust geometry and radiative transfer effects, which may in part explain the observed differences.

In order to understand the role of dust and to correct the integrated light from galaxies, we need to gain a better understanding of the processes shaping the dust attenuation curve. The dust attenuation curve can be derived from the stellar light of galaxies, but it requires wide wavelength coverage and sufficient spectral resolution. Both requirements are needed to break degeneracies with other modeling parameters, such as stellar age and star formation timescale (e.g., Labbé et al. 2005) and to directly detect the UV dust bump. This combination has recently become feasible with the completion of the NEWFIRM Medium-Band Survey (NMBS; Whitaker et al. 2011; van Dokkum et al. 2009). In this Letter we use well-sampled composite spectral energy distributions (SEDs) constructed from the NMBS photometry (Kriek et al. 2011), in combination with the flexible stellar population synthesis (Conroy et al. 2009, 2010b; Conroy & Gunn 2010) models, to constrain the dust attenuation curve in 0.5 < z < 2.0 galaxies.

2. DATA

The NMBS is a 0.5 deg2 photometric survey in the COSMOS and AEGIS fields, unique for its five customly designed medium-band near-infrared filters. The data obtained using these filters are combined with optical-to-MIR photometry. For this study we make use of the NMBS catalogs in the
Figure 1. Composite SEDs for three arbitrarily chosen galaxy types, ordered by increasing value of $A_V$. The top panels show the full wavelength range and the middle panels zoom in on the gray open box in the rest-frame UV. The gray shaded area indicates the region around H$\alpha$. The best-fit FSPS models for different dust attenuation curves are overplotted. We explore the Calzetti law (light blue), the MW law (purple), and a dust law in which the slope ($\delta$) and strength of the UV bump ($E_b$) are free parameters (red). The corresponding attenuation curves are shown in the bottom panels. The parameterization of the slope ($\delta = [-0.8, 0.2]$) and bump strength ($E_b = [0, 4]$) are represented by the dashed-dotted and solid gray curves in the bottom panels. Both the Calzetti and the MW dust law provide poor fits in the rest-frame UV.

(A color version of this figure is available in the online journal.)

COSMOS field, which include medium-band photometry at optical wavelengths as well. When no spectroscopic redshifts are available, we use photometric redshifts (EAzY; Brammer et al. 2008), which have an accuracy of $\Delta z/(1 + z) < 0.02$ (Whitaker et al. 2011; Kriek et al. 2011; Brammer et al. 2011). The high quality of the NMBS photometry has been illustrated in van Dokkum et al. (2010) and Whitaker et al. (2010, 2012).

In Kriek et al. (2011) we divided the NMBS galaxies at $0.5 < z < 2.0$ and with a $S/N_K > 25$ into different spectral classes based on their observed optical-to-IRAC SEDs. Each spectral class contains 22–455 individual galaxies of similar spectral shape. For each class, we constructed a composite SED by de-redshifting and scaling the observed photometry. These composite SEDs are basically low-resolution spectra ($R \lesssim 25$, Figure 1), and show many spectral features among which H$\alpha$ which is blended with [N\textsc{ii}] and [S\textsc{ii}] and the blended [O\textsc{iii}] and H$\beta$ lines. Continuum and absorption features are also visible, among which Mg\textsc{ii}, the Balmer and 4000 Å breaks, and the dust absorption feature at 2175 Å.

3. Constraining the Dust Attenuation Law

We constrain the dust attenuation curve by fitting the composite SEDs with FSPS models in their default setting. These
settings include a low contribution from thermally pulsing asymptotic giant branch stars (e.g., Conroy & Gunn 2010; Kriek et al. 2010; Zibetti et al. 2013). We assume a Chabrier (2003) initial mass function (IMF) and an exponentially declining star forming history. Our result is robust against the choice of the IMF, as it primarily affects the mass-to-light ratio, and has little impact on the shape of the SED. We explore a grid of stellar ages, star formation timescales, and three different metallicities (0.0096, 0.019 (Z⊙), & 0.03). We use the stellar population fitting code FAST (Kriek et al. 2009), which is based on a simple χ² minimization. For the photometric uncertainties we assume a flat error in Fλ of 3% of the average flux, in order to ensure that the full SED shape will be taken into account in the fit. 

If we would use the formal errors, the fit would be driven completely by the very small error bars at longer wavelengths. The region around Hα is masked in the fit. The confidence intervals are calibrated using Monte Carlo simulations.

First, we explore the MW (Cardelli et al. 1989) and the Calzetti dust attenuation curves, and find the best-fit stellar population model when allowing all other parameters to vary. Next, we parameterize the dust attenuation curve following the prescription by Noll et al. (2009):

\[ A(\lambda) = \frac{A_V}{4.05} (k(\lambda) + D(\lambda)) \left( \frac{\lambda}{\lambda_V} \right)^{\delta} \]  

(1)

with D the Lorentzian-like Drude profile to parameterize the UV bump, defined as:

\[ D(\lambda) = \frac{E_b(\lambda, \Delta \lambda)^2}{(\lambda^2 - \lambda_0^2)^2 + (\lambda \Delta \lambda)^2}. \]  

(2)

For the central wavelength of the dust bump \( \lambda_0 \) we adopt 2175 Å. For \( \Delta \lambda \), the FWHM of the bump, we assume a value of 350 Å as found by Noll et al. (2009) from a stack of a spectra of high-redshift galaxies and by Seaton (1979) for the MW UV bump. We explore a grid of values for \( E_b \) and \( \delta \), while leaving all other fitting parameters free. All attenuation curves are implemented as uniform screens.

In Figure 1 we show the best-fit stellar population models for three composite SEDs, for the three different attenuation laws. This figure illustrates that for all three SEDs the Calzetti and MW law provide poor fits at rest-frame UV wavelengths. When leaving both the slope and bump strength as free parameters, we can reproduce their full SED shapes.

The best-fit values for \( E_b \) and \( \delta \) for all composite SEDs with \( A_V > 0 \) are shown in Figure 2(a). There is a clear correlation between both properties, described by the following linear fit:

\[ E_b = (0.85 \pm 0.09) - (1.9 \pm 0.4) \delta. \]  

(3)

SED types with steeper attenuation curves have stronger UV bumps, while shallower attenuation curves go together with weaker UV bumps.

4. CORRELATIONS WITH SPECTRAL TYPE

In the previous, section we found a large variety in dust attenuation curves among the different SED types. In order to examine whether the shape of the dust law correlates with spectral type, we show both \( E_b \) and \( \delta \) as a function of the equivalent width of Hα (\( W_{\text{Hα}} \)) in Figures 2(b) and (c). Similar to the specific star formation rate (SFR), \( W_{\text{Hα}} \) is a

![Figure 2](image-url)
measure of the present to past star formation in a galaxy. This measurement directly follows out of the composite SEDs, and thus is independent of the FSPS modeling. We do note that $W_{H\alpha}$ may include some contamination by [N II] and [S II], and thus may be slightly overestimated.

Figures 2(b) and (c) show that the shape of attenuation curve correlates with spectral type. Galaxies with higher values for $W_{H\alpha}$ have shallower attenuation curves with weaker UV bumps. The only significant outlier to this trend is SED type 8, which is best fit by a shallow dust slope ($\delta \sim 0.2$), while having a low $W_{H\alpha}$. The least square fits give the following relations:

$$E_b = (2.2 \pm 0.3) - (1.1 \pm 0.3) \left( \frac{W_{H\alpha}}{100 \, \text{Å}} \right)$$

$$\delta = (0.33 \pm 0.04) \left( \frac{W_{H\alpha}}{100 \, \text{Å}} \right) - (0.41 \pm 0.04).$$

Our findings suggest that the dust attenuation curve should not be treated as a universal function, but should be related to the spectral type. In the next section we examine the implications of our results.

5. IMPLICATIONS

Comparing broadband SEDs or spectra with stellar population synthesis (SPS) models is a popular method to derive galaxy properties. In this procedure, the shape of the dust attenuation curve is almost always held fixed. Here we examine possible biases introduced by assuming the popular Calzetti dust attenuation law. Figure 3 shows the difference in best-fit galaxy properties for a free dust law compared to when assuming the Calzetti law. This figure illustrates that a fixed dust law may introduce systematic biases. $A_V$ and the specific SFR could be significantly overestimated for galaxies with high $W_{H\alpha}$, while stellar mass may be slightly underestimated. For lower values of $W_{H\alpha}$ we find the opposite effect. However, this trend is driven by only one SED type (12), which was previously noted in Kriek et al. (2011) as being poorly fit by any SPS model, and thus this trend is not significant.

At high-redshift dust attenuation corrections are frequently derived from the UV $\beta$ slope ($F_{\lambda} \propto \lambda^{\beta}$), adopting the relation of Meurer et al. (1999). This relation was based on a UV slope measured by masking the UV bump and other features. In contrast, the measurements at high redshift are based on a small number of broadband filters (e.g., Reddy et al. 2010; Bouwens et al. 2012). In Figure 4 we use the composite SEDs to assess how the UV bump may influence the measurement of the UV slope, and hence the dust correction. In the top panel we show the difference in derived $A_V$ using the relation by Meurer et al. (1999) vs. the strength of the dust feature for all composite SEDs with $A_V > 0.5$. This figure illustrates that dust corrections based on photometric measurements may be significantly underestimated, resulting in underestimated SFRs. However, the choice of filters in this illustration may possibly represent the worst case scenario, and different filters, redshifts, or the availability of multiple filters will lead to smaller biases.
panel, we show an example composite SED, the corresponding photometric measurements for two rest-frame UV filters for this SED, and the slopes based on the composite SED (dashed line) and photometric datapoints (dotted lines). In the lower panel, we show the difference in the derived attenuation correction—based on the two UV slopes—versus the strength of the dust feature, for all composite SEDs with $A_V > 0.5$. This figure illustrates that the presence of a dust feature may lead to underestimated dust corrections, and thus underestimated SFRs. Stronger dust features clearly result in larger biases.

However, the illustration in Figure 4 is probably a worst case scenario, where only two filters are used, and the reddest filter completely overlaps with the UV bump. Several studies use three to four photometric bands (e.g., Bouwens et al. 2012) to measure the UV slope, resulting in more robust measurements. Furthermore, $W_{\text{H}$\alpha$}$ increases with increasing redshift (e.g., Stark et al. 2013), and thus at a redshift of $z = 6$ (used in the illustration in Figure 4) or higher the bump may be insignificant. We do note, though, that the utility of the UV slope for estimating dust attenuation has been called into question before (e.g., Kong et al. 2004; Johnson et al. 2007; Conroy et al. 2010a; Gonzalez-Perez et al. 2013).

6. DISCUSSION

The primary result of this Letter is that the shape of the dust attenuation curve varies with spectral type. This trend may be explained by differences in the dust-to-star geometry, which could result in age-dependent extinction and variations in the scattering and absorption of radiation (e.g., Chevallard et al. 2013). In particular, a two-component dust model (e.g., Calzetti et al. 1994; Charlot & Fall 2000; Granato et al. 2000; Wild et al. 2011), in which all stars are attenuated by the diffuse ISM, while younger stars experience additional attenuation due to dust in their short-lived birth clouds, naturally produces the observed trends. This model predicts variation with galaxy inclination as well, as the optical depth of the diffuse component is larger for edge-on galaxies. In Figure 5, we show Hubble Space Telescope (HST) morphologies (Scoville et al. 2007) as function of $E_\alpha$ and $\delta$. This figure illustrates that face-on and/or more active galaxies on average have shallower attenuation curves with weaker UV bumps. Similar trends are also seen in local galaxies (Wild et al. 2011). Only SED type 8, which we mentioned before, does not follow the trends.

The observed correlations between the attenuation curve and the specific SFR may also reflect variations in the grain size distribution. This could arise from a changing balance between grain formation, growth, and destruction with star formation history (e.g., Gordon et al. 2003). See Conroy (2013) for more discussion on the proposed explanations.

Our values for $E_\alpha$ and $\delta$ are in the same range to those found by Buat et al. (2012), who fit the photometry of individual galaxies in the GOODS-S field. They also find weaker UV bump strengths in galaxies with larger specific SFRs (see also Wild et al. 2011). Buat et al. (2012) find no correlation though between the slope and the dust bump for their sample. This may not be surprising, as for individual galaxies the photometric resolution and signal-to-noise ratio ($S/N$) may not be sufficient to resolve the bump and to break modeling degeneracies. As a result the scatter in the measurements will be large, and possible trends may be washed out.

While the study presented in this Letter has been enabled by stacking SEDs of similar type, this is also a weakness, as we may be combining galaxies with different attenuation curves. Furthermore, the rest-frame wavelength coverage is not the same for all redshifts, and at bluer wavelengths the SEDs are dominated by the redshifted galaxies in our sample. Thus, extending this study to shorter wavelengths, using Galaxy Evolution Explorer data will give a more robust and representative measurement of the UV attenuation curve.

Another drawback is that we only look at the attenuated and not at the re-emitted light. In a future study we will extend the composite SEDs to longer wavelengths as well, so that we can simultaneously study the dust attenuation and emission as a function of spectral type.

7. SUMMARY

In this Letter, we use composite SEDs, constructed from NMBS photometry, to study variations in the dust attenuation curve in $0.5 < z < 2.0$ galaxies. Based on similarities between the full SED shapes, we have divided galaxies in different spectral classes and stacked the photometry. As each spectral type contains galaxies which span a range in redshift, the resulting SEDs are well sampled in wavelength and show various spectral features among which H$\alpha$ and the 2175 Å dust feature.

We fit all composite SEDs with FSPS models, while exploring attenuation curves with varying slopes and UV bump strengths. The MW and Calzetti law provide poor fits at UV wavelengths for nearly all SED types. We find that the strength of the UV bump and the slope of the curve are strongly correlated, with steeper slopes having stronger UV dust bumps. Moreover, the shape of the dust attenuation curve correlates with the equivalent width of H$\alpha$ (i.e., specific SFR), with higher $W_{\text{H}$\alpha$}$ galaxies having shallower dust attenuation curves and weaker UV bumps. The average attenuation law has a UV bump strength of $\sim 25\%$.
of the MW bump, and a slope in between the SMC and the MW extinction curve.

Our results are consistent with a two-component dust model, in which all stars are attenuated by the diffuse ISM, while young stars experience extra attenuation due to dust in their short-lived birth clouds. A qualitative analysis of the morphologies further supports this picture, as edge-on galaxies have on average steeper dust curves and stronger UV bumps. A varying grain size distribution may also contribute to the observed correlations with Heα equivalent width.

A non-universal dust attenuation curve has numerous implications for galaxy evolution studies. By assuming a universal dust law, derived stellar population properties will suffer from systematic biases. For example, for the Calzetti law, the dust content and specific SFR could be significantly overestimated. Stellar mass measurements are more robust, and are only slightly underestimated. Furthermore, the biases vary with spectral type.

The presence of the dust bump also complicates dust corrections based on the UV β slope. In the worst case scenario, when the redder filter overlaps with the bump, A_{1600} could be underestimated by ~1 mag, resulting in significantly underestimated SFRs. On a positive note, the observed variation should motivate theoretical work aimed at embedding self-consistent dust models into galaxy formation models.

We thank the members of the NMBS and COSMOS teams for releasing high-quality multi-wavelength data sets to the community, and the referee for a constructive report. M.K. acknowledges support from HST grant HST-AR-12847.01-A. C.C. acknowledges support from the Alfred P. Sloan Foundation.
