SUMMARY

Introduction Dirofilariasis is a zoonosis caused by nematodes from the genus *Dirofilaria*, which is a parasite in dogs and other canids, and humans get infected by a mosquito bite. In Europe, the number of patients outside the endemic area is increasing. So far, more than 2,850 cases of human dirofilariasis have been reported worldwide. In the last 20 years, we have had only two confirmed cases in our institution. The disease is manifested in a cutaneous, visceral, and ocular form. From the initial infection, the first symptoms can take several years to manifest. The diagnosis can be confirmed histologically, morphologically, and/or by molecular techniques. The treatment includes surgical removal of the parasite and antiparasitic therapy.

Case outline The paper presents two cases of *Dirofilaria repens* infection. The first patient had a migratory nodular facial skin change for several years. After the skin induration incision in the zygomatic region, a 7-cm-long worm was extracted, later identified as *Dirofilaria repens*. The pathohistological finding of the extirpated change showed that it was a granuloma inflammation. The second case was a patient with a persistent cough and hemoptysis, with a morphologically verified nodular change in the pulmonary parenchyma. The pathohistological finding of the extirpated change showed a chronic granulomatous inflammation and the presence of parasites. The treatment of both patients resulted in a complete recovery without complications.

Conclusion In case of subcutaneous nodules or unclear lung changes, dirofilariasis should be considered. Video-assisted thoracoscopic surgery is the leading diagnostic surgical procedure concerning dirofilariasis, and a significant therapeutic modality.

Keywords: dirofilariasis; parasitosis; video-assisted thoracoscopic surgery

INTRODUCTION

Dirofilariasis is a zoonosis caused by nematodes from the genus *Dirofilaria*. The parasite is transmitted to humans from infected animals, most often dogs, accidentally, by an infected mosquito bite. The infection includes only one worm, and it may take several decades until the first symptoms occur. The disease is benign and very rare outside the endemic area. In Europe, the number of patients has been steadily increasing for the last ten years [1]. There are three forms of the disease, subcutaneous, visceral and ocular.

By the year 2012, there were 1,782 cases of human dirofilariasis reported, out of which 1,410 in Europe, and 372 in the USA [2]. In Serbia, 37 cases were reported by 2014 [3]. The diagnosis is based on anamnestic data, clinical course, possible parasite visualization, surgical extirpation, pathohistological verification, and, rarely, serological diagnosis. The treatment can be surgical and conservative. Prophylaxis includes the treatment and prophylaxis in dogs as a reservoir, the suppression of mosquitoes as vectors, and the protection of humans by means of repellents.

CASE REPORT

This paper presents two cases of *Dirofilaria repens* infection, which were confirmed at the Clinic for Infectious and Tropical Diseases of the Military Medical Academy in the last 20 years.

The first case was diagnosed in 1998 in a woman aged 64 from the village of Kusadak, located in the vicinity of Belgrade. She had had a migratory nodular facial skin change for several years. Since her youth, the patient had been having a dry, irritating cough, and later some problems in the form of redness and itching of the skin. Three years prior to diagnosis, some migratory tumor changes occurred on the scalp, and then she developed swelling and redness of the upper eyelid region. Further on, pain, redness and skin induration of the right zygomatic region occurred. When pressure was applied to the induration, a vital 7-cm-long parasite was extracted (Figure 1). The identification was carried out at the Institute of Medical Biochemistry of the Military Medical Academy where *D. Repens* female was confirmed. The patient’s clinical findings were dominated by a zygomatic bone swelling, together with induration and hyperemia. All laboratory findings were within reference values, while serological analyses were negative. Histopathological examination of the extirpated change showed granuloma inflammation.

The second case was diagnosed in 2018 in a 72-year-old male from Belgrade. He first came to the doctor’s due to persistent cough and hemoptysis. Morphological tests and multislice
computed tomography (MSCT) of the thorax showed a lobulated, infiltrative change 16 × 16 × 11 mm in segment VI of the right lower lung lobe, showing signs of infiltration of the surrounding parenchyma, followed by minimal pneumonitis (Figure 2). Video-assisted thoracoscopic surgery (VATS) was performed and a knot tissue sample 27 × 15 mm in size was obtained. Histopathological examination showed chronic granulomatous inflammation with necrosis similar to dirofilariasis. The patient was feeling well all the time and all his laboratory parameters were within reference values. Albendazole therapy was used for 28 days. In the further course of the disease, the patient lost all subjective symptoms, while the definitive suspicion of a malignant neoplasm was removed by the control MSCT thorax examination.

**DISCUSSION**

Natural hosts of *Dirofilaria* are dogs and wild canids, such as foxes, wolves, and raccoons. Humans get infected by a mosquito bite. In Serbia, every species of mosquitoes transmits the parasite [4]. The infection in humans is most commonly caused by three species: *D. immitis*, *D. repens*, and *D. tenius*. *Dirofilaria immitis* usually causes human pulmonary dirofilariasis throughout the world, while subcutaneous dirofilariasis caused by *D. repens* is recorded in Europe [5]. These two species are able to cause both pulmonary and extrapulmonary infection. It most commonly occurs in adults between the ages of 21 and 60 years (ESDA), but the case of a 14-month-old child with *Dirofilaria* in the scrotum region has also been described, which is its most common localization in children [6]. Women are more likely to be infected than men, but without a significant statistical difference. Generally, it occurs rarely in people, has a benign character, and, in most cases, the diagnosis is made by histopathological examination, and extremely rarely, as in our first case, by the evacuation of a live parasite.

The endemic areas for dirofilariasis are Asia, Africa, the Mediterranean, but in the past decade, there has been an increasing number of cases reported outside the endemic area, i.e. in the region of northern and central Europe [1]. The highest percentage of cases was registered in Italy (66%), followed by France (22%), Greece (8%), and Spain (4%) [7]. *D. repens* spread faster than *D. immitis* from the endemic areas of southern Europe to northern Europe [8].

Risk factors and predispositions are not clear and well defined. The number of dogs in a given area, the prevalence of infection, the number of infected mosquitoes, and human exposure can contribute to the spread of the disease in certain geographical areas. It is believed that the risk of human pulmonary dirofilariasis is greater in periods of natural disasters, most likely due to the occurrence of floods, more mosquitoes, and an increase in the number of stray dogs [1]. In Serbia, during a period of 10 years, dog seroprevalence went from 7% to 26.9% (2004–2014) [9].

The anatomical localization as well as the clinical presentation of this parasite varies. Ophthalmic presentation accounts for 40% of reported cases. Nodular localization is found on the head and neck in 18.9–25.3%, in the extremities in 14.8–22.1%, in the torso in 11.4–11.8%, in male genitalia in 2.9–4.1%, in female breasts in 2.5–2.7% of the cases. Cases of unencapsulated forms in peritoneum have also been described in 0.6% of cases [10]. A large majority of patients with dirofilariasis had one painful subcutaneous nodule, without signs of infection. In the case of ocular localization, symptoms are the feeling of burning, itching, and pain in the eye. The majority of patients with pulmonary dirofilariasis are asymptomatic, while 38% have symptoms in the form of cough, fever, and hemoptysis [8].

The diagnosis of the disease is based on the possible visualization of the parasite, as well as the pathohistological verification. VATS has been proven to be the best, both diagnostic and therapeutic, method, because in this way a safe differential diagnosis is performed concerning malignant diseases, tuberculosis, pulmonary thromboembolism, and Wegener's granulomatosis [2].

There are serological tests, but they are rarely available, are not satisfactory, give cross-positive results with other filariases, most commonly with *Toxocara canis* nematode [2]. Bearing in mind all the aforementioned, we may conclude that serological tests should be used exclusively as...
In conclusion, the treatment is both surgical and conservative. Conservative treatment involves the use of ivermectin or albendazole for four weeks. In many cases, causative therapy is not necessary before the surgery. Tumolskaya et al. [6] suggest that the patient should be given a single dose of ivermectin with three doses of diethylcarbamazine if there is a marked suspicion of dirofilariasis. The importance of dirofilariasis is increasing with regard to global warming, increased number of pets, and human migrations. The number of the diseased is rising and the geographic distribution is changing, especially in northern Europe, outside the endemic area. In case of subcutaneous nodules or unclear lung changes, dirofilariasis should be considered. VATS is the leading diagnostic surgical procedure concerning dirofilariasis, and a significant therapeutic modality.
