Abstract. We investigate the self-locomotion of an elongated microswimmer by virtue of unidirectional tangential surface treadmilling. We show that the propulsion could be almost frictionless, as the microswimmer is propelled forward with the speed of the backward surface motion, i.e. it moves through an almost quiescent fluid. We investigate this swimming technique using the special spheroidal coordinates and also find an explicit closed-form optimal solution for a two-dimensional treadmiller via complex-variable techniques. Slender-object surface treadmilling is a particularly efficient mode of locomotion because the viscous drag is determined by the smallest length scale of the object rather than by the largest scale, as is the usual case for low Reynolds number flow.

1. Introduction

Tiny swimmers, be they micro-organisms or microbots, live in a world dominated by friction [1]. In this world, technically, the world of low Reynolds numbers, motion is associated with energy dissipation. In the absence of external energy supply objects rapidly come to rest [2]. It is both conceptually interesting, and technologically important, for example in applications to nanomedicine [3], to try and understand what classes of strategies lead to effective swimming in a setting dominated by dissipation. A particularly promising class of strategies is where the motion is, in a sense, only apparent; where a shape moves with little or no motion of material particles.

The wheel is the mechanical application of this strategy and it is instructive to examine it from this point of view. The (unholonomic) constraint of rolling without slipping comes about because of the large friction between the wheel and the surface supporting it. Nevertheless, a wheel can roll with little or no dissipation of energy. One way to view this is to note that the motion of the point of contact is only apparent. The point of contact moves, even though the part of the wheel in contact with the surface, is momentarily at rest.

An example closer to the world of low Reynolds numbers is the actin-based propulsion of the leading edge of motile cells [4], intracellular bacterial pathogens [5] and biomimetic cargoes [6]–[8]. The actin filaments assemble themselves from the ambient solution at the front end and disassemble themselves at the rear end. Here again, it is only shape that is moving and in principle at least the energy invested at the front end can be recovered at the rear end. (There are thermodynamics and entropic issues that we shall not consider here). Apparent motions seem to be good at fighting dissipation [9].

Here we shall focus on a closely related mode of locomotion: surface treadmilling. In surface treadmilling the swimmer moves without a change of shape, by a tangential surface motion as depicted in figure 1. Surface is generated at the front end and is consumed at the rear end.5 In contrast to actin and microtubules, the surface treadmilling does not rely on the exchange of material with the ambient fluid. (The swimmer needs, of course, an inner mechanism to transfer

5 Alternatively, we may think of a a slender microbot that is topologically equivalent to a toroidal swimmer proposed by Purcell [1], i.e. the surface is not created or destroyed, but rather undergoes a continuous tank-treading motion.
Figure 1. The schematic snapshots of the ‘cigar-shaped’ microswimmer propelled by surface treadmilling. The dashed circles represent material points of the boundary displaced to the left with the treadmilling speed (equal to $u(\zeta)$ in the co-moving coordinate frame), as the swimmer is propelled to the right with the velocity $U$. The boundary points remain almost stationary in the laboratory frame.

material from its rear to its front.) It is intuitively clear that a needle shaped swimmer undergoing treadmilling can move with very little dissipation because the ambient fluid is almost quiescent and there is almost no relative motion between the surface of the swimmer and the fluid. One cannot make treadmilling completely non-dissipative because there is always some remanent dissipation associated with the motion of the front and rear ends. The main question that we shall address here is how one can quantitatively estimate this remanent dissipation.

Let us first consider simple qualitative estimates of the power dissipated by viscosity in treadmilling. Consider a rod-like slender swimmer of length $\ell$, thickness $d$ with rounded caps undergoing treadmilling at velocity $U$. It is reasonable to assume (and the analysis in the following section can be used to justify) that all the dissipation is associated with the rounded ends. Hence, by dimensional analysis, the power dissipated in treadmilling is of the order of $\mu d U^2$ where $\mu$ is the viscosity coefficient. Let us compare this with the power needed to drag the ‘frozen’ treadmiller. By slender body theory [10] the power needed to drag the tube with velocity $U$ is $\sim \mu \ell U^2 / \log (2\ell/d)$. Hence the ratio of power invested in dragging and swimming scales like $(\varepsilon \log 1/\varepsilon)^{-1}$ and can be made arbitrarily large. Here $\varepsilon = d/\ell$ is the aspect ratio of the swimmer.

One can now ask if there are slender treadmillers that are arbitrarily better than the slender rod-like treadmiller above? Consider now an elongated ellipsoidal microswimmer whose surface is given by $z^2/b^2 + r^2/a^2 = 1$ where $r^2 = x^2 + y^2$. Let us assume again, that the viscous dissipation is a result of a tip propulsion, and estimate the position of the tip from the condition $|dr/dz| = 1$. It can be readily demonstrated that in the case of $\varepsilon = a/b \ll 1$ the tip is located at a distance of $b(1 - \frac{1}{2} \varepsilon^2)$ from the centre and its typical width scales as $a\varepsilon$. Therefore, applying
the same arguments as before, the dissipation rate should then scale as $P \sim \mu a \varepsilon U^2$ and the ratio of power expanded in dragging and swimming becomes $\frac{b \mu U^2 / \log (2b/a)}{\mu a \varepsilon U^2} \sim \frac{1}{\varepsilon^2 \log 1/\varepsilon}$.

We shall see, by a more accurate analysis, that for a prolate spheroid the ratio of power in treadmilling to dragging is of the order of $(\varepsilon \log \varepsilon)^{-2}$. In the following sections we shall analyse two models of treadmillers in three and two dimensions, respectively. The quantitative analysis establishes the basic properties of surface treadmilling of slender objects as put forward above. Namely, that the optimal surface motion is nearly constant-speed far from the poles of the swimming object, and creates a flow field where the fluid is nearly quiescent far from the poles. As a consequence, the swimmer is propelled forward with a velocity very close to the negative of the main-body surface velocity, while dissipation occurs only in a small region near the poles. This is in contrast to drag dissipation which occurs everywhere near the surface of the object. Hence, locomotion by surface treadmilling is more efficient than dragging by a factor related to the aspect ratio of the swimmer, which can be made in principle as large as desired by making the swimmer slender enough.

2. 3D microswimmer

2.1. The theoretical framework

We model the microswimmer as a prolate spheroid swimming in an unbounded fluid by continuous tangential surface motion. The Cartesian-coordinate system $(x_1, x_2, x_3)$ is fixed with the centre $O$ of the spheroid (see figure 1). A modified orthogonal prolate spheroidal coordinate system $(\tau, \zeta, \phi)$ with unit vectors $(e_\tau, e_\zeta, e_\phi)$ is defined via the relations

$$x_1 = c(\tau^2 - 1)^{1/2} \{1 - \zeta^2\}^{1/2} \cos \phi, \quad x_2 = c(\tau^2 - 1)^{1/2} \{1 - \zeta^2\}^{1/2} \sin \phi, \quad x_3 = c\tau \zeta,$$

where $-1 \leq \zeta \leq 1 \leq \tau < \infty, 0 \leq \phi \leq 2\pi$ and $c$ is the semi-focal distance [11]. The coordinate surfaces $\tau = \tau_a = \text{const}$ are a family of confocal spheroids, $x_3^2/a^2 + (x_1^2 + x_2^2)/b^2 = 1$, centred at the origin with major and minor semi-axis given by $b = c\tau_a$ and $a = c(\tau_a^2 - 1)^{1/2}$, respectively, and the aspect ratio $\varepsilon = a/b = [1 + (c/a)^2]^{-1/2}$. The Lamé metric coefficients are

$$\hat{H}_\tau = c\frac{\{\tau^2 - \zeta^2\}^{1/2}}{\{\tau^2 - 1\}^{3/2}}, \quad \hat{H}_\zeta = c\frac{\{\tau^2 - \zeta^2\}^{1/2}}{\{1 - \zeta^2\}^{1/2}}, \quad \hat{H}_\phi = c\{\tau^2 - 1\}^{1/2} \{1 - \zeta^2\}^{1/2}.$$

We assume that a steady axisymmetric flow has been established around the microswimmer as a result of the tangential surface treadmilling with a uniform far-field velocity $U$ (equal to the laboratory frame propulsion speed) in the negative $x_3$-direction. The low-$Re$ incompressible flow is governed by the Stokes and continuity equations,

$$\Delta \mathbf{v} = \mu \text{ grad } p, \quad \text{div } \mathbf{v} = 0, \quad (1)$$

respectively, accompanied by the boundary condition at the swimmer surface $\tau = \tau_a$

$$\mathbf{v} = u(\zeta) \, e_\zeta. \quad (2)$$

New Journal of Physics 9 (2007) 145 (http://www.njp.org/)
Since the flow is axisymmetric we introduce the scalar stream-function \( \Psi \) (unique up to an additive constant) that satisfies the continuity equation

\[
v = v_\tau e_\tau + v_\zeta e_\zeta = \text{curl} \left( \frac{1}{H_\psi} \Psi e_\psi \right).
\]

The velocity components are readily obtained from (3) as

\[
v_\tau = \frac{1}{H_\zeta H_\psi} \frac{\partial \Psi}{\partial \zeta}, \quad v_\zeta = -\frac{1}{H_\tau H_\psi} \frac{\partial \Psi}{\partial \tau}.
\]

The vorticity field can be obtained from (3) as

\[
\omega = \text{curl} \ v = -\frac{1}{H_\psi} E^2 \Psi e_\psi,
\]

where the operator \( E^2 \) is given by

\[
E^2 = \frac{1}{c^2 (\tau^2 - \zeta^2)} \left[ (\tau^2 - 1) \frac{\partial^2}{\partial \tau^2} + (1 - \zeta^2) \frac{\partial^2}{\partial \zeta^2} \right].
\]

Following the standard procedure, the pressure is eliminated from the Stokes equation by applying the curl operator to both sides, with conjunction with (4) this yields the equation \( E^4 \Psi = 0 \) for the stream-function. The boundary conditions (2) at the microswimmer surface \( \tau = \tau_a \) in terms of the stream-function become

\[
\Psi = 0, \quad \partial_\tau \Psi = -c^2 (\tau_a^2 - \zeta^2)^{1/2} (1 - \zeta^2)^{1/2} u(\zeta),
\]

and the conditions at infinity (\( \tau \to \infty \)) are \( v_\tau \sim -U \zeta, \ v_\zeta \sim -U (1 - \zeta^2)^{1/2} \).

The solution for \( \Psi \) that is regular on the axis and at infinity, and also even in \( \zeta \) can be derived from a general semiseparable solution [11, 12],

\[
\Psi = -2c^2 U G_2(\tau) G_2(\zeta) + \sum_{m=2,4,...}^\infty \{ A_m H_m(\tau) G_m(\zeta) + C_m \Omega_m(\tau, \zeta) \},
\]

where \( \Omega_m(\tau, \zeta) \) is a solution of \( E^4 \Psi = 0 \) composed from spheroidal harmonics that decay at infinity (see appendix), and \( G_m \) and \( H_m \) are the Gegenbauer functions of the first and the second kind, respectively. The coefficients \( A_m \) can be expressed in terms of \( C_m \) and \( U \) via the use of the boundary condition \( \Psi = 0 \) at \( \tau = \tau_a \). Substituting (6) into (5) we arrive after some algebra at the tridiagonal infinite system of equations for \( U \) and the coefficients \( C_m \),

\[
\xi_m^{(-)} C_{m-2} + \xi_m^{(0)} C_m + \xi_m^{(+)} C_{m+2} = b_m, \quad m = 2, 4, \ldots.
\]
Here \( C_0 = -c^2 U \), \( \mathcal{E}_m^{(0, \pm)} \) are known functions of \( \tau_a \) given in appendix, and

\[
b_m = \frac{c^2}{2} m(m-1)(2m-1) \int_{-1}^{+1} \left\{ \frac{\tau_a^2 - \xi^2}{1 - \xi^2} \right\}^{1/2} u(\xi) G_m(\xi) \, d\xi. \tag{8}
\]

Regularity of \( \Psi \) implies that the admissible solution of (7) should satisfy \( C_m H_m(\tau_a) \rightarrow 0 \) as \( m \rightarrow \infty \) while the exponentially growing solution with \( C_m \sim O((\tau_a + \sqrt{\tau_a^2 - 1})^{2m}) \) should be discarded.

The viscous drag force exerted on the prolate spheroid (in the \( x_3 \)-direction) is solely determined by the \( C_2 \)-term in (6) corresponding to a monopole (Stokeslet) velocity term decaying like \( 1/r \) far from the particle, \( F = - (4\pi \mu/c) C_2 \) [13]. Either \( F \) or \( U \) can be specified in addition to the surface velocity, \( u(\zeta) \). In the swimming problem \( F = C_2 = 0 \), and \( u(\zeta) \) determines the propulsion velocity \( U \).

The problem of the ‘frozen’ spheroid (i.e. \( u(\zeta) = 0 \)) in the uniform ambient flow \(-Ue_3\) corresponds to substituting \( b_m = 0 \), \( m \geq 2 \) in (7). In this case the equations for \( C_m \) can readily be solved yielding the well-known result for \( \Psi \) and the drag force [13],

\[
F = \frac{8\pi \epsilon U}{(1 + \tau_a^2) \coth^{-1} \tau_a - \tau_a}. \tag{9}
\]

2.2. Propulsion velocity

In order to determine the velocity of propulsion of the microswimmer freely suspended in the viscous fluid, one must solve equations (7) with \( C_2 = 0 \) as the particle is force (and torque) free. Let us consider the following velocity distribution at the boundary

\[
u(\zeta) = -2\tau_a u_s (\tau_a^2 - \zeta^2)^{-1/2} (1 - \zeta^2)^{-1/2} G_2(\zeta), \tag{10}
\]

where \( u_s \) is a typical velocity of surface treadmilling and \( G_2(\xi) = \frac{1}{2} (1 - \xi^2) \). One may verify that for a sphere (\( c/a \rightarrow 0 \)) \( u(\zeta) = u_s \sin \theta \), while for an elongated swimmer \( u(\zeta) \simeq u_s \) almost everywhere except the near vicinity of the poles \( \zeta = \pm 1 \) (\( u(\zeta) \) is plotted in figure 4 for \( c = 2.5a \)). More generally it can be readily shown that the solution satisfying (5) and (10) is given by (6) with \( C_m = 0 \), \( \forall m; \quad A_m = 0 \), \( m \geq 4 \),

\[
\Psi(\tau, \zeta) = \left\{ -2c^2 U G_2(\tau) + A_2 H_2(\tau) \right\} G_2(\zeta), \tag{11}
\]

where the coefficients \( A_2 \) and \( U \) read

\[
A_2 = -2c^2 u_s \tau_a (-1 + \tau_a^2), \quad U = u_s \left\{ \tau_a^2 - \tau_a (-1 + \tau_a^2) \coth^{-1} \tau_a \right\}. \tag{12}
\]

For the slender treadmiller the asymptotic behaviour of swimming speed can be estimated from (12) by using \( \tau_a = 1/\sqrt{1 - \varepsilon^2} \simeq 1 + \varepsilon^2/2 \) where \( \varepsilon = a/b \ll 1 \); the swimming speed
approaches the boundary velocity \( u_s \) as \( U/u_s \simeq 1 - \varepsilon^2 |\log \varepsilon| \). Note that \( U \) can be related to the surface motion via the use of the Lorentz reciprocal theorem [10],

\[
\mathbf{\hat{F}} \cdot \mathbf{U} = -\int_{S} (\mathbf{\hat{\sigma}} \cdot \mathbf{n}) \cdot \mathbf{u} \, dS, \tag{13}
\]

where \((\mathbf{\hat{u}}, \mathbf{\hat{\sigma}})\) is the velocity and stress field corresponding to translation of the same shaped object when acted upon by an external force \( \mathbf{\hat{F}} \). For purely tangential surface motion considered in this work we have \((\mathbf{\hat{\sigma}} \cdot \mathbf{n}) \cdot \mathbf{u} = \mathbf{\hat{\sigma}}_{\tau \xi} u(\zeta), \) where

\[
\mathbf{\hat{\sigma}}_{\tau \xi} = \frac{\hat{\mathbf{H}}_{\tau}}{\hat{\mathbf{H}}_{\xi}} \frac{\partial}{\partial \xi} \left( \frac{\hat{v}_\tau}{\hat{H}_{\tau}} \right) + \frac{\hat{\mathbf{H}}_{\xi}}{\hat{\mathbf{H}}_{\tau}} \frac{\partial}{\partial \tau} \left( \frac{\hat{v}_\tau}{\hat{H}_{\tau}} \right). \]

We calculate the local tangential stress component \( \mathbf{\hat{\sigma}}_{\tau \xi} \) from the solution corresponding to streaming past a rigid prolate spheroid, while \( \mathbf{\hat{F}} \) is given by (9). Substitution into (13) with \( dS = \hat{\mathbf{H}}_\phi \hat{\mathbf{H}}_\xi \, d\phi \, d\xi \) yields after some algebra

\[
U = -\frac{\tau_{a}}{2} \int_{-1}^{1} \left( \frac{1 - \zeta^2}{\tau_{a}^2 - \zeta^2} \right)^{1/2} u(\zeta) \, d\zeta, \tag{14}
\]

which holds for an arbitrary tangential boundary velocity \( u(\zeta) \). In the special case of \( u(\zeta) \) given by (10) it can be readily demonstrated that integration yields the propulsion speed (12). Also, (14) actually solves the infinite tridiagonal system (7), since knowing \( U, F \) (i.e. \( C_0, C_2 \)) one can iteratively obtain all the other \( C_m \)s by direct substitution. The scaled swimming speed of the microswimmer is depicted in figure 2 as a function of the scaled elongation. The values of the propulsion velocity corresponding to a spherical swimmer \((c = 0)\) and a slender swimmer \((c \gg a)\) can be determined via (13) without invoking special spheroidal coordinates. For a sphere, the local traction force \( \mathbf{\hat{\sigma}} \cdot \mathbf{n} = -3\mu a \hat{U} \) and \( \mathbf{\hat{F}} = -6\pi \mu a \hat{U} \) and thus the self-propulsion velocity can be found as [14]

\[
U = -\frac{1}{4\pi a^2} \int_{S} \mathbf{u} \cdot \mathbf{e} \, dS,
\]

where \( \mathbf{e} \) is the unit vector in the direction of locomotion. Substituting \( \mathbf{u} = u_s \sin \theta \mathbf{e}_\theta \) and \( \mathbf{e} = \mathbf{e}_\phi \cos \theta - \mathbf{e}_\theta \sin \theta \), where \( \theta \) is the spherical angle measured with respect to \( \mathbf{e} \), we arrive at \( U = \frac{1}{2} \int_{0}^{\pi} u_s \sin^3 \theta \, d\theta = \frac{1}{2} u_s \) in agreement with the result shown in figure 2.

The drag force exerted on the rod-like microswimmer upon translation along its major axis with velocity \( \mathbf{U}^{\parallel} \) is given by \( \mathbf{\hat{F}}^{\parallel} \approx -4\pi \mu a \mathbf{U}^{\parallel}/(\varepsilon \log 1/\varepsilon) \) and the local friction force is \( \mathbf{\hat{\sigma}} \cdot \mathbf{n} \approx -\mu \mathbf{U}^{\parallel}/(a \log 1/\varepsilon) \). Thus, from (13) follows

\[
U \approx -\frac{1}{4\pi ab} \int_{S} \mathbf{u} \cdot \mathbf{e} \, dS.
\]

For the ‘needle-shaped’ microswimmer the surface velocity \( \mathbf{u} = u(\zeta)\mathbf{e}_\zeta \simeq -u_s \mathbf{e} \) over almost the whole surface, it follows that \( U \approx u_s \). As seen in figure 2 the propulsion velocity \( U/u_s \rightarrow 1 \) as \( c/a \) grows and equals to 0.95 already at \( c \simeq 5.3a \). As intuitively expected, the microswimmer is self-propelled forward with the velocity of the surface treadmilling, while the boundary velocity in the laboratory frame is (almost) zero.

\[\text{\footnotesize\textsuperscript{6}}\text{In the laboratory frame the velocity at the surface is a superposition of the translational velocity} \ U \text{and purely tangential motions} \ u.\]
2.3. Swimming efficiency

Since the fluid around the elongated microswimmer propelled by continuous surface treadmilling is almost quiescent, except for in the vicinity of the poles, it is natural to expect low viscous dissipation and high hydrodynamic swimming efficiency. Several definitions of hydrodynamic efficiency have been proposed [14]–[16] here we follow the definition $\delta = F \cdot U / P$, where $P$ is the energy dissipated in swimming with velocity $U$, and the expression in the numerator is the work expended by dragging the ‘frozen’ swimmer at velocity $U$ upon action of an external force $F$ [14]. $\delta$ is dimensionless and compares the self-propulsion with dragging (some authors use the reciprocal efficiency $1/\delta$). The higher $\delta$ the more efficient the swimmer is. For an axisymmetric swimmer propelled along the symmetry axis, $F \cdot U = RU^2$, where the scalar $R$ is the appropriate hydrodynamic resistance. The work done by an arbitrary shaped swimmer and dissipated by viscosity in the fluid is given by

$$P = - \int_S \left( \sigma \cdot n \right) \cdot v \, dS = 2\mu \int_V E : E \, dV,$$

where $E$ is the rate-of-strain tensor, $V$ is the fluid volume surrounding the swimmer and $S$ its surface. Expressing the product $E : E$ as $\sum \omega_i \omega_i + 2(\partial_i v_j)(\partial_j v_i)$ allows $P$ to be re-written for microswimmers self-propelled by purely tangential motions $u$ as [14]

$$P = \mu \int_V \omega^2 \, dV + 2\mu \int_S u^2 \kappa_s \, dS,$$

where $\kappa_s = -(\partial s/\partial s) \cdot n$ is the curvature measured along the path of the surface flow, expressible in terms of the unit tangential and normal vectors, $s$ and $n$, respectively. Let us now estimate $\delta$ of the spheroidal treadmiller described in the previous subsection. For a prolate spheroid $s = e_\zeta$, $n = e_\tau$, respectively, and $\kappa_s$ can be calculated as

$$\kappa_s = \frac{1}{H_{\zeta} H_{\tau}} \frac{\partial^2 H_{\zeta}}{\partial \tau^2} \bigg|_{\tau = \tau_s} = \frac{\tau_a \sqrt{\tau^2_a - 1}}{c(\tau^2_a - \xi^2)^{3/2}}.$$
Figure 3. The swimming efficiency of the spheroidal microswimmer, $\delta$, versus the scaled elongation $c/a$ (linear-log plot). The solid line corresponds to the exact calculation, the dashed line is the asymptotic result.

Since the solution (12) corresponds to irrotational flow\(^7\), i.e. $\omega = 0$ the volume integral in (15) drops out. Substituting the expression for the surface velocity (10) and $\kappa_s$ into the surface integral in (15) we find

$$P = 4\pi \mu c u_s^2 \left( \tau_a^2 - 1 \right) \left\{ (1 + \tau_a^2) \coth^{-1} \tau_a - \tau_a \right\}. \tag{16}$$

Collecting the expressions for the drag force (9), velocity of self-propulsion (12) and the dissipation (16) one can compute the swimming efficiency,

$$\delta = \frac{RU^2}{P} = \frac{2 \left\{ \tau_a^2 - \tau_a (\tau_a^2 - 1) \coth^{-1} \tau_a \right\}^2}{\left( \tau_a^2 - 1 \right) \left\{ (1 + \tau_a^2) \coth^{-1} \tau_a - \tau_a \right\}^2}. \tag{17}$$

$\delta$ is plotted as a function of the elongation $c/a$ in figure 3. Evidently, $\delta$ grows unbounded as $c/a \to \infty$ does, corresponding in the limit to a frictionless swimmer. For the spherical treadmiller $\delta$ can be calculated from (15) with $u = u_s \sin \theta \, e_\theta$, $u_s = \frac{3}{2} U$ and $\kappa_s = 1/a$, $P = 2\mu \int_S \frac{9}{4} U^2 \sin^2 \theta \, \frac{1}{a} dS = 12 \pi \mu a U^2$. Dividing $6\pi \mu a U^2$ by $P$ we find $\delta = \frac{1}{2}$ in agreement with (17) (see figure 3) and the theoretical bound (i.e. $\delta \leq \frac{3}{4}$) of [14].

For the slender swimmer the asymptotic behaviour of $\delta$ is estimated from (17) as

$$\delta \simeq \frac{1}{2} \frac{1}{\left( \varepsilon \log \varepsilon \right)^2}. \tag{18}$$

This result is shown in figure 3 as a dashed line. For comparison, the efficiency of spherical squirmers self-propelled by propagating surface waves along their surface (the mathematical model of cyanobacteria [17]) has the upper bound $\delta \leq \frac{3}{4}$, while numerically calculated values of $\delta$ do much worse and the corresponding swimming efficiency is usually less than 2% [14]. Swimming by surface treadmilling is remarkably more efficient than the rotating helical

\(^7\) Since $E^2(H_m G_m) = 0$ the vorticity $\omega$ is determined by the $C_m$, $m \geq 4$ terms in (6).
flagellum [18], beating flexible filament [19], Percell’s ‘three-link swimmer’ [20] or locomotion by virtue of shape strokes [15, 16]. Surface treadmilling is probably superior to any inertialess swimming techniques proposed so far.

Also, the swimming efficiency of the ellipsoidal treadmiller is superior by a factor of $\left(\frac{\varepsilon}{\log \frac{1}{\varepsilon}}\right)^{-1}$ over the estimate of $\delta$ corresponding to the rod-like treadmiller with rounded ends derived from purely scaling arguments in the introduction. Therefore, the geometry (via $\kappa_s$) plays an important role in minimizing the dissipation in surface treadmilling, which is rather surprising since the drag force on slender nonmotile object does not depend on its shape to the first approximation.

2.4. Optimal swimming

We can set an upper bound on $\delta$ for a spheroidal microswimmer in terms of surface integrals of an arbitrary velocity $u(\zeta)$ analogously to [14]. The power dissipated in self-propulsion is bounded from below according to (15) by

$$\mathcal{P} \geq 2\mu \int u^2\kappa_s dS = 4\pi\mu c \tau_a \left(\tau_a^2 - 1\right) \int_{-1}^{+1} \frac{u^2(\zeta)}{\tau_a^2 - \zeta^2} d\zeta,$$

where we used the previously derived result for $\kappa_s$. The power expanded in dragging at the same speed is found from (9) and (14) as

$$\mathcal{R} U^2 = \frac{2\pi c \mu \tau_a^2}{(1 + \tau_a^2) \coth^{-1} \tau_a - \tau_a} \left[ \int_{-1}^{+1} \left\{ \frac{1 - \zeta^2}{\tau_a^2 - \zeta^2} \right\}^{1/2} u(\zeta) d\zeta \right]^2.$$  \hspace{1cm} (19)

Combining the last two results we obtain an upper bound on $\delta$ as

$$\delta \leq \frac{\tau_a}{(\tau_a^2 - 1)(1 + \tau_a^2) \coth^{-1} \tau_a - \tau_a} \left\{ \int_{-1}^{+1} \left( \frac{1 - \zeta^2}{\tau_a^2 - \zeta^2} \right)^{1/2} u d\zeta \int_{-1}^{+1} \frac{u^2}{\tau_a^2 - \zeta^2} d\zeta \right\}.$$

The term in the figure brackets can be shown to be bounded from above by $\frac{2}{3}$ while its maximum is obtained for $u(\zeta) = u_s \sqrt{1 - \zeta^2} \sqrt{\tau_a^2 - \zeta^2}$ corresponding to the two-term boundary velocity expansion with $b_2, b_4 \neq 0, b_m = 0, m \geq 6$ in (8) (and, thus, representing a rotational flow). Thus, for an elongated swimmer (\( \tau_a \to 1 \)) we arrive at

$$\delta \leq \frac{1}{3\varepsilon^2 \log \frac{1}{\varepsilon}}$$

which does better than (18) by a factor of $(\log \frac{1}{\varepsilon})^{-1}$ and is also superior to the scaling estimate for the rod-like swimmer by a factor of $O(1/\varepsilon)$. Note that the asymptotic behaviour $\delta \sim \frac{1}{\varepsilon^2 \log 1/\varepsilon}$ was derived from simple scaling arguments in the introduction.
It can be demonstrated that the surface velocity (10) is not optimal, i.e. it does not minimize \( \mathcal{P} \) for a prescribed propulsion speed \( U \). To see this consider the slightly perturbed boundary velocity

\[
\begin{equation}
\begin{aligned}
u(\xi) &= \frac{-2\tau_a}{(\tau_a^2 - \xi^2)^{1/2} (1 - \xi^2)^{1/2}} \{u_2G_2(\xi) + u_4G_4(\xi)\},
\end{aligned}
\end{equation}
\]

such that \( |u_1| \ll |u_2| \) and \( u_2 \sim u_4 \). The solution of the linear problem (7) yields \( |\omega| = \mathcal{O}(u_4) \) and therefore, the volume integral in (15) is \( \mu \int \omega^2 \, dV = \mathcal{O}(u_4^2) \). The surface integral in (15) can be calculated as

\[
2\mu \int_S u^2 \kappa_s \, dS = u_2^2 I_2(\tau_a) + u_2 u_4 I_4(\tau_a) + \mathcal{O}(u_4^2),
\]

where \( I_2(\tau_a) \) is given by (16) and \( I_4 \) is some other function of \( \tau_a \). The velocity of propulsion can be found in a close form as \( U = u_2 F_2(\tau_a) + u_4 F_4(\tau_a) \) from (14), where \( F_2 \) is equal to the expression in the figure brackets in (12) and \( F_4 \) is some other function of \( \tau_a \). As the propulsion velocity to be fixed, we require \( U = u_4 F_2 \). This yields dissipation

\[
\mathcal{P} = u_2^2 I_2 + u_4 u_4 \left( I_4 - 2 \frac{F_4}{F_2} I_2 \right) + \mathcal{O}(u_4^2),
\]

where the function in the brackets can be shown to be positive and bounded for all \( \tau_a > 1 \), and vanishes only at \( \tau_a \to 1 \). Therefore, one can always choose some \( u_4 < 0 \) such that \( \mathcal{P} < u_2^2 \) leading to reduction in the dissipation compared with (16). The above perturbation analysis shows that, quite surprisingly, vorticity production could bring a reduction in viscous dissipation, leading to more efficient swimming.

To address the question of optimal swimming we consider an arbitrary boundary velocity via the expansion, that meets all the above requirements for regularity and evenness in \( \xi \),

\[
\begin{equation}
\begin{aligned}
u(\xi) &= \frac{-2\tau_a}{(\tau_a^2 - \xi^2)^{1/2} (1 - \xi^2)^{1/2}} \sum_{m=2,4,...}^{L} u_m G_m(\xi),
\end{aligned}
\end{equation}
\]

where it follows from (8) that \( u_m = -b_m/(2c^2 \tau_a) \). To find a set of Fourier coefficients \( u_m \), \( m = 2, 4, 6, \ldots L \) corresponding to the optimal swimming, one should minimize the dissipation integral, \( \mathcal{P} \), while keeping the propulsion speed \( U \) fixed. The dissipation integral \( \mathcal{P} = -\int_S \sigma_{\xi \xi} \, dS \) being bilinear in \( u_4 \), can be expressed as \( \mathcal{P} = \frac{1}{2} \sum u_i \mathcal{P}_{ij} u_j \). Note however that the tangential stress \( \sigma_{\xi \xi} \) at the surface of the microswimmer requires the knowledge of the velocity gradient at the surface (rather than velocity alone). Alternatively, since the optimal velocity field is rotational, calculation of \( \mathcal{P} \) from (15) requires the knowledge of vorticity everywhere.

The propulsion velocity given by (14) is linear in \( u_4 \), i.e. \( U = \sum_j F_j u_j \). The optimal set of coefficients \( u_i \) is to be determined from \( \frac{\partial}{\partial u_i} (\mathcal{P} - \lambda U) = 0 \), or just from \( \sum_j \mathcal{P}_{ij} u_j = \lambda \mathcal{F}_i \), where \( \lambda \) is a Lagrange multiplier. We found the closed form optimal solution for the two-term boundary velocity (21), while for \( L > 4 \) closed form expressions are cumbersome, and numerical solutions were derived instead. Analogously to the theory for a 2D swimmer (see the next section), where the explicit optimal solution was shown to acquire an infinite number of harmonics in the expansion for the boundary velocity, increasing the truncation level \( L \) in (21) will further
improve the efficiency of swimming, though the enhancement appears to be minor. To illustrate this, we calculate the optimal solution upon varying $L$. The optimal boundary velocity upon varying $L$ is depicted in figure 4 for the elongation of $c = 2.5a$ and compared with the one-term expression (10). The scaled dissipation integral, $\mathcal{P}/\mu au_s^2$, is plotted versus $c/a$ upon varying $L$ in figure 5. It can be readily seen that the convergence with respect to $L$ is rather fast; the deviation between the results corresponding to $L = 8$ and 10 is less than 1% for all $c/a$ and it vanishes at both limits $c = 0$ and $c/a \to \infty$. Thus, the ‘intuitive’ one-term boundary velocity (21), that yields $\delta \sim (\varepsilon \log \varepsilon)^{-2}$ (see figure 3) is nearly optimal for a wide range of elongations and likely so for all elongations.

Figure 4. The optimal boundary velocity $u$ versus the spheroidal coordinate $\zeta$ for elongation $c = 2.5a$ at various truncation levels: $L = 4$ (red) and $L = 10$ (blue). The black line correspond to the one-term boundary velocity (10).

Figure 5. The dissipation integral versus the scaled elongation corresponding to optimal swimming at various truncation levels (linear–log plot): $L = 4$ (red) and $L = 10$ (blue). The black line refers to (16).
3. 2D microswimmer

In 2D, the Stokes equations (1) are conveniently handled by employing complex variables [15, 16], [20]–[23]. This allows explicit solution of the optimization problem for the elliptical treadmiller.

Denoting \( v = v_x + iv_y \) and \( \partial = \frac{1}{2}(\partial_x - i\partial_y) \), the Stokes equations become 2\( \mu \partial \bar{\partial} v = \bar{\partial} p \), \( \text{Re} \partial v = 0 \). The most general solution to this (with \( p \) real) is \( v = g + \bar{f} - \frac{z}{\zeta} g' \), \( p = -4\mu \text{Re}(g') \) where \( g, f \) are any pair of holomorphic functions. Solutions corresponding to multivalued \( g, f \) are also legitimate (provided the resulting \( v, p \) are single valued). It can be shown (using (22) below) that the monodromy of \( g \) (and of \( \bar{f} \)) around a closed curve gives the total force exerted by the fluid on the interior of the curve. In particular in swimming problems this force must vanish and \( g, f \) are therefore always single valued.

The element of force \( dF \equiv dF_x + idF_y \) acting on a length element \( dz = dx + idy \) of the fluid can be expressed in terms of \( v, P \) and hence in terms of \( g, f \). Straightforward calculation shows that the relation is

\[
dF = i p \, dz + (2i\mu \bar{\partial} v) \, d\bar{z} = 2i\mu \, d(v - 2g).
\] (22)

Note that here \((dx, dy)\) is tangent rather than the normal to the segment.8

We consider a 2D swimmer shaped as an ellipse of semi-axes \( b, a = 1 \pm \alpha \) (with \( 0 \leq \alpha < 1 \)) situated in the complex \( z = x + iy \) plane. It is then convenient to define a new complex coordinate \( \zeta \) by the relation \( z = \zeta + \frac{\alpha}{\zeta} \). As \( \zeta \) ranges over the region \( |\zeta| > 1 \) the corresponding \( z \) ranges over the area outside the swimmer. In particular the swimmer boundary corresponds to the unit circle \( \zeta = e^{i\theta} \). Note that if we consider \( g, f \) as functions of \( \zeta \) rather than \( z \) then the general solution of the Stokes equations becomes

\[
v = g + \bar{f} - \frac{\zeta + \alpha/\zeta}{1 - \alpha/\zeta^2} g'.
\] (23)

In the swimmer frame of reference, the boundary condition at infinity \( v(\infty) = -U \) (where \( U \) is the laboratory-frame swimming speed) implies Laurent expansions

\[
f = \sum_{n=1}^{\infty} a_n \zeta^{-n}, \quad g = -U + \sum_{n=1}^{\infty} b_n \zeta^{-n},
\] (24)

where \( U \) is arbitrarily appended to \( g \).

The boundary condition on the swimmer surface is fulfilled by matching \( v(\zeta) \) to a prescribed boundary motion \( v|_{\zeta=\zeta_0} = w(\theta) = \sum_{n=-\infty}^{\infty} w_n e^{in\theta} \). It is useful to express \( w(\theta) \) as \( w = w_+(\zeta) + w_-(\zeta) = e^{i\theta} \) where \( w_- = \sum_{n=0}^{\infty} w_{-n} \zeta^{-n}, \quad w_+ = \sum_{n=1}^{\infty} w_n \zeta^{-n} \) are both analytic outside the unit circle. Substituting (24) into (23) and matching on the unit circle we find

\[
g(\zeta) = w_-(\zeta), \quad f(\zeta) = w_+(\zeta) + \frac{\zeta(1 + \alpha \zeta^2)}{\zeta^2 - \alpha} w'_-(\zeta).
\]

8 The sign convention here is that \( dF \) is the force exerted by the lhs of the (oriented) segment \( dz \) on its rhs.
In particular the swimming velocity is determined by the constant term in this expansion
\[ U = -w_0. \]

The corresponding dissipation is calculated using (22) as
\[
P = -Re \oint \bar{v} dF = 2 \mu \Im \oint \bar{w} d(2g - w) = 4 \pi \mu \sum_{n=-\infty}^{\infty} |n| |w_n|^2.
\]

Let us next focus on the case of an ellipse swimming by surface treadmilling. The
boundary velocity \( w(\theta) \) being tangent to the swimmer boundary is expressible as
\[ w = \frac{dz}{d\theta} u(\theta) = i(\zeta - \alpha/\zeta)u(\theta) \]
for some real-valued function \( u(\theta) \). Since we consider only swimmers symmetric
with respect to the \( x \)-axis, we assume \( u(\theta) \) to be an odd function allowing us to write it
as
\[ u = \sum_{n} u_n \sin(n\theta) = \frac{1}{2i} \sum_{n} u_n (\zeta^n - \zeta^{-n}). \]

In these terms the swimming velocity turns into
\[ U = -w_0 = \frac{1}{2} \left( 1 + \alpha \right) u_1 \]
while the dissipation takes the form
\[
P = 2 \pi \mu \sum_{n} \left[ (1 + \alpha^2)u_n^2 - 2\alpha u_{n-1}u_{n+1} \right].
\]

Which may also be written as \( P = \frac{1}{2} \sum P_{ij}u_iu_j \) for a corresponding tridiagonal matrix \( P_{ij} \).

The optimal swimming technique for a given \( \alpha \) is the one that minimizes the dissipation
while keeping the swimming velocity \( U = \frac{1}{2} (1 + \alpha)u_1 \) fixed. The minimizer is the solution of
\[
\frac{\partial}{\partial u_i} (P - \lambda u_1) = 0 \quad \forall \lambda \text{ with } \lambda \text{ being a Lagrange multiplier, or just}
\]
\[
\sum_j P_{ij}u_j = \lambda \delta_{i,1}. \quad (25)
\]

It is readily seen that the coefficients \( u_k \) with even \( k \) are not relevant to the optimal swimming
and should be set to zero to minimize viscous dissipation. (This is also clear from the fact that \( u_{2k} \)
correspond to flows which are antisymmetric with respect to the \( y \)-axis.)

Denoting \( b_k \equiv u_{2k+1} \), \( k \geq 0 \) and writing \( \lambda = 2u_s \pi \mu (1 + \alpha^2) \) with \( u_s \) an arbitrary normalization
constant having dimensions of velocity we obtain from (25) the recursion relation
\[
(2k + 1)b_k - \xi(kb_{k-1} + (k + 1)b_{k+1}) = u_s \delta_{k,0},
\]
where \( \xi = \frac{2u_s}{1+\alpha^2} \). Multiplying by \( x^k \) and summing over \( k \) this transforms into a differential equation for the generating function \( B(x) = \frac{1}{u_s} \sum_{k=0}^{\infty} b_k x^k \),
\[
h(x) B'(x) + \frac{1}{2} h'(x) B(x) + 1 = 0,
\]
where we defined \( h(x) \equiv \xi(x - \alpha)(x - \frac{1}{\alpha}) \). The general solution to this is
\[ B(x) = -\frac{1}{\sqrt{h(x)}} \int_{0}^{x} \frac{dx'}{\sqrt{h(x')}} = \frac{2}{\xi \sqrt{x-x_+}} \log \left( \frac{\sqrt{x-x_-} + \sqrt{x}}{\sqrt{x_+} - x_-} \right), \]
where \( x_+ = \frac{1}{\alpha} - x \) and \( x_- = \alpha - x \). The corresponding swimming velocity and the dissipation are, respectively,

\[
U = \frac{(1 + \alpha)u_1}{2} = \frac{u_s}{2} (1 + \alpha) B(0) = \frac{u_s (1 + \alpha)}{2 \xi} \log \left( \frac{1 + \alpha}{1 - \alpha} \right),
\]

\[
\mathcal{P} = \frac{1}{2} \sum P_{ij} u_i u_j = \frac{1}{2} \lambda u_1 = \pi \mu (1 + \alpha^2) u_2^2 B(0) = \frac{\pi \mu}{2 \alpha} u_s^2 (1 + \alpha^2) \log \left( \frac{1 + \alpha}{1 - \alpha} \right).
\]

Therefore, combining the last two results yields

\[
\mathcal{P} = \frac{2 \alpha}{(1 + \alpha)^2} \log \left( \frac{1 + \alpha}{1 - \alpha} \right).
\]

We recall that in 2D the dragging problem admit no regular solution within the Stokes approximation\(^9\). Thus defining the swimming efficiency as \( \delta = (\mathbf{F} \cdot \mathbf{U}) / \mathcal{P} = \mathcal{R} U^2 / \mathcal{P} \) makes no sense in the present 2D context in which \( \mathbf{F}, \mathcal{R} \) are not defined. This may be considered as a mere issue of normalization. We therefore use here an alternative definition of swimming efficiency [16] where

\[
\delta^* = \frac{4 \pi \mu U^2}{\mathcal{P}} = \frac{(1 + \alpha)^2}{2 \alpha} \log \left( \frac{1 + \alpha}{1 - \alpha} \right). \tag{26}
\]

In the slender limit, \( \alpha \to 1 \), or, \( a \equiv \frac{1 - \alpha}{1 + \alpha} = \varepsilon \to 0 \), as the ellipse degenerates into a needle, the efficiency grows logarithmically unbounded as

\[
\delta^* \simeq 2 \log(1/\varepsilon).
\]

It may be of interest to note that truncating our expansion to include any finite number of modes would lead to \( B(x) \) which is not only polynomial in \( x \) but also algebraic in \( \alpha \). This then implies that the (truncated) efficiency \( \delta^* \propto B(0) \) would be algebraic in \( \alpha \) implying that (26) must be modified to a bounded expression. Thus (in contrast to the 3D case) one cannot obtain the correct asymptotic efficiency without retaining all the modes.

The optimal boundary velocity may be found explicitly as

\[
w(\theta) = \frac{dz}{d\theta} \sum u_k \sin(k\theta) = \frac{dz}{d\theta} \sum b_k \frac{e^{i(2k+1)\theta} - e^{-i(2k+1)\theta}}{2i} = u_s \frac{dz}{d\theta} \text{Im} \left\{ e^{i\theta} B \left( e^{2i\theta} \right) \right\}.
\]

Using the explicit expression we have for \( B(x) \) and \( \frac{dz}{d\theta} \) we find the absolute value of \( w \) is given by

\[
|w| = u_s \frac{1 + \alpha^2}{\sqrt{\alpha}} \log \left| \frac{\sqrt{\alpha - e^{2i\theta}} + \sqrt{1/\alpha - e^{2i\theta}}}{\sqrt{1/\alpha - \alpha}} \right|,
\]

while its direction is known to be tangential. Thus, in the limit \( \varepsilon \to 0 \) one finds (provided \( \varepsilon \ll \theta, |\pi - \theta| \)) that

\[
|w / U| \simeq 1 + \frac{\log |2 \sin \theta|}{\log 1/\varepsilon},
\]

and the boundary velocity approaches the constant \( U \) though only at a logarithmic rate.

\(^9\) This is known as the Stokes paradox and can be resolved by noting that far from the object the quadratic term \((v \cdot \nabla) v \sim (U \cdot \nabla) v \sim \mu \Delta v \) cannot be neglected [24].

*New Journal of Physics* 9 (2007) 145 (http://www.njp.org/)
4. Concluding remarks

In this paper we examined the propulsion of an elongated microswimmer by virtue of continuous surface treadmilling. As the slenderness increases, the hydrodynamic disturbance created by the surface motion diminishes, i.e. the microbot is propelled forward with the velocity of the surface treadmilling, while the surface, except the near vicinity of the poles, remains stationary in the laboratory frame. As a result of this, the ‘cigar-shaped’ treadmiller is self-propelled through an almost quiescent fluid yielding very low viscous dissipation. The calculation of optimal hydrodynamic efficiency of the 3D and the 2D microswimmers reveals that the proposed swimming technique is not only superior to various motility mechanisms considered in the past, but also performs much better than dragging under the action of an external force.

Appendix

The spheroidal harmonics $\Omega_m(\tau, \zeta)$ in (6) are given by

$$\Omega_2 = \beta_2^* \left[ H_2(\tau) G_4(\zeta) + H_4(\tau) G_2(\zeta) \right] + \frac{1}{6} G_1(\tau) G_2(\zeta),$$

and

$$\Omega_m = -\alpha_m^* \left[ H_{m-2}(\tau) G_m(\zeta) + H_m(\tau) G_{m-2}(\zeta) \right] + \beta_m^* \left[ H_{m+2}(\tau) G_m(\zeta) + H_m(\tau) G_{m+2}(\zeta) \right], \quad m \geq 4,$$

where the coefficients $\alpha_m^*$ and $\beta_m^*$ are

$$\alpha_m^* = \frac{(m-3)(m-2)}{2(2m-1)(2m-3)^2}, \quad \beta_m^* = \frac{(m+1)(m+2)}{2(2m-1)(2m+1)^2}.$$

The coefficients $A_m$ in (6) can be expressed in terms of $C_m$ and $U$ as

$$A_2 = \left\{ 2e^2 U G_2 - C_2 \left( \beta_2^2 H_4 + \frac{1}{6} G_1 \right) + C_4 \alpha_4^2 H_4 \right\} H_2^{-1},$$

$$A_m = -C_{m-2} \beta_{m-2}^* \frac{H_{m-2}}{H_m} + C_m \left( \alpha_m^* \frac{H_{m-2}}{H_m} - \beta_m^* \frac{H_{m+2}}{H_m} \right) + C_{m+2} \alpha_{m+2}^* \frac{H_{m+2}}{H_m}, \quad m \geq 4.$$

The coefficients of the tridiagonal system (7) are given by

$$\mathcal{E}_2^{(-)} = \left( P_1 - \frac{G_2}{H_2} \frac{Q_1}{Q_1} \right), \quad \mathcal{E}_2^{(0)} = \beta_2^* \left( Q_3 - H_4 \frac{Q_1}{H_2} \right) + \frac{1}{6} \left( 1 - \frac{G_1}{H_2} \frac{Q_1}{Q_1} \right),$$

$$\mathcal{E}_m^{(-)} = \beta_{m-2}^* \left( Q_{m-3} - \frac{H_{m-2}}{H_m} \frac{Q_{m-1}}{Q_{m-1}} \right), \quad m \geq 4,$$

$$\mathcal{E}_m^{(0)} = -\alpha_m^* \left( Q_{m-3} - \frac{H_{m-2}}{H_m} Q_{m-1} \right) + \beta_m^* \left( Q_{m+1} - \frac{H_{m+2}}{H_m} \frac{Q_{m-1}}{Q_{m-1}} \right), \quad m \geq 4,$$

$$\mathcal{E}_m^{(+)} = -\alpha_{m+2}^* \left( Q_{m+1} - \frac{H_{m+2}}{H_m} \frac{Q_{m-1}}{Q_{m-1}} \right), \quad m \geq 2,$$

where $P_n$, $Q_n$, $G_n$ and $H_n$ correspond to the values of the appropriate Legendre and Gegenbauer functions at $\tau = \tau_0$.
