We have found a quantum cloning machine that optimally duplicates the entanglement of a pair of $d$-dimensional quantum systems. It maximizes the entanglement of formation contained in the two copies of any maximally-entangled input state, while preserving the separability of unentangled input states. Moreover, it cannot increase the entanglement of formation of all isotropic states. For large $d$, the entanglement of formation of each clone tends to one half the entanglement of the input state, which corresponds to a classical behavior. Finally, we investigate a local entanglement cloner, which yields entangled clones with one fourth the input entanglement in the large-$d$ limit.

I. INTRODUCTION

The no-cloning theorem\(^\text{[1]}\) precludes a perfect cloning of arbitrary quantum states. However, an imperfect cloning is possible and various quantum cloning machines (QCM), which duplicate quantum states with the highest fidelity, have been proposed following the seminal paper of Buzek and Hillery\(^\text{[2]}\). Recently, the question of whether quantum entanglement can be cloned or not was addressed: “if a quantum operation can be found that perfectly duplicates the entanglement of all ME states, then it is necessary does not preserve separability”. A QCM was proposed that optimally (but imperfectly) clones the entanglement of two-dimensional bipartite states (qubits) while preserving separability.

In the present paper, we extend these results to pairs of $d$-dimensional quantum systems, with arbitrary $d$. We show that a (symmetric) cloning machine can be defined, which maximizes the amount of entanglement of the two clones of ME states, while producing separable clones in the case of unentangled input states. We analyze the entanglement of the clones in terms of fidelity, but show that optimizing the cloning machine in terms of fidelity actually leads to maximizing the entanglement of formation of the clones provided that we restrict to cloning machines that are covariant under local unitaries. We then compare the resulting optimal $d \times d$ entanglement cloner to a “local” cloning transformation that can be achieved by applying a separate universal cloning machine to each component of the bipartite system.

II. COVARIANT CLONER UNDER LOCAL UNITARIES IN DIMENSION $d \times d$

Following the ideas presented in\(^\text{[2]}\), we seek for a cloning transformation that (i) preserves separability, and (ii) maximizes the entanglement of the two clones resulting from any ME input state. We will characterize a cloner by considering the transformation of an input that is maximally entangled with a reference system. By projecting the reference onto (the complex conjugate of) the input state, one gets the operation of the cloner on this state. The general form for such a cloning transformation is defined in the computational basis $\{|i\rangle\}$ by the state

$$|S\rangle_{R,a,b,A} = \sum_{i,j,k,l} s_{ijkl} |i\rangle_R |j\rangle_a |k\rangle_b |l\rangle_A \quad (1)$$

where $R$ denotes the reference system, $a$ and $b$ stand for the two clones, and $A$ corresponds to the ancilla. All the summations here are $d^2$-dimensional since all the states involved are $d^2$-dimensional bipartite states, e.g., $|i\rangle = |i_A\rangle|i_B\rangle$. Thus, each index $i$, $j$, $k$, or $l$ actually represents a couple of indices running each from 0 to $d - 1$, e.g., $i = \{i_A,i_B\}$, with $i_A, i_B \in [0; d-1]$. Of course, the index $A$ stands for Alice’s component of the bipartite states, while $B$ stands for Bob’s component.

As mentioned above, the joint state of the two clones and the ancilla is obtained by performing an appropriate projection on the reference system. Thus, for an input state $|\Phi\rangle = \sum_i n_i |i\rangle$, the result of the cloning transformation is of the form

$$|\chi\rangle = \mathcal{R} \langle \Phi^* |S\rangle_{R,a,b,A} = \sum_{i,j,k,l} s_{ijkl} n_i |j\rangle_a |k\rangle_b |l\rangle_A \quad (2)$$

Then, the state of any one of the clones is further obtained by tracing out the ancilla and the other clone. This entanglement cloning transformation is shown in Fig. 1.
Next, we impose the following covariance condition on our cloning machine. Since we know that any local unitary operation acting on the A and B components of a bipartite state preserves its entanglement, we require that any such transformation acts similarly on the clones. This condition amounts to imposing

\[ |S\rangle_{\mathcal{R},a,b,A} = U^* \otimes U \otimes U^* |S\rangle_{\mathcal{R},a,b,A} \]  

(3)

where \( U \) is the product of any two unitary transformations acting separately on each \( d \)-dimensional component of the bipartite state, that is

\[ U = U_A \otimes U_B \]  

(4)

where the indices \( A \) and \( B \) denote Alice’s and Bob’s components. Defined in this way, the operator \( U \) possesses a \( SU(d) \otimes SU(d) \) symmetry. The covariance property implies that \( s_{ijkl} \) in (1) is an invariant tensor of rank 4, which satisfies

\[ s_{ijkl} = U_{i'i}^* U_{j'j}^* U_{k'k}^* U_{l'l}^* s_{i'j'k'l'} \]  

(5)

where \( U^* \) denotes the matrix element-wise complex conjugate of \( U \) with respect to the computational basis. (Here, the summation over all repeated indices is implicit.) The matrix elements \( U_{ij} = \langle i | U | j \rangle \) satisfy \( U_{ik}^* U_{kj} = \delta_{ij} \). If the transformation is real (i.e., \( U_{ij} = U_{ij}^* \)), then the invariant tensors for Alice’s component are of the general form \( \delta_{i'A_j} \delta_{k'A_l} \) or \( \delta_{i'A_j} \delta_{k'A_l} \), or \( \delta_{i'A_j} \delta_{k'A_l} \) (see (4)). For a complex transformation on Alice’s component, the terms of the form \( \delta_{i'A_j} \delta_{k'A_l} \) are excluded, so we are left with the two remaining terms. Then, for a tensor product of (complex) unitary transformations on Alice’s and Bob’s components, a general form for the invariant tensor is

\[ s_{ijkl} = A \delta_{i'A_j} \delta_{k'A_l} \delta_{B_iB_j} \delta_{B_kB_l} + B \delta_{i'A_j} \delta_{k'A_l} \delta_{B_iB_k} \delta_{B_jB_l} + C \delta_{i'A_k} \delta_{j'A_l} \delta_{B_iB_j} \delta_{B_kB_l} + D \delta_{i'A_k} \delta_{j'A_l} \delta_{B_iB_j} \delta_{B_kB_l}. \]  

(6)

For a symmetric cloner, the output state must be invariant under the interchange of the two clones, i.e., under permutations \( (j_A, j_B) \leftrightarrow (k_A, k_B) \). This implies that \( A = C \) and \( B = D \), so we are left with only two parameters \( A \) and \( B \) to be determined.

**III. OPTIMAL ENTANGLEMENT CLONER IN DIMENSION \( d \times d \)**

The covariance condition (3) guarantees that our QCM transforms all states which are equivalent up to local unitaries (which have therefore the same entanglement) into equally entangled clones. In particular, the clones of all ME states will be equally entangled. Then, a cloner that is optimized on a particular ME input state will be optimal for all ME states. We choose as the initial \( d \times d \) ME state

\[ |\Phi\rangle = \sum_{i_A,i_B=0}^{d-1} n_{i_Ai_B} |i_A\rangle |i_B\rangle \]  

(7)

where \( n_{i_Ai_B} = \delta_{i_Ai_B} / \sqrt{d} \). As we shall show later on, we can maximize the entanglement of the clones simply by optimizing our QCM in terms of the fidelity of the clones, \( F = \langle \Phi | \rho_0 | \Phi \rangle \),

(8)

where

\[ \rho_0 = \text{Tr}_{A,B} [ |\chi\rangle \langle \chi| ] \]  

(9)

is the state of clone \( a \). For the ME state (7), this fidelity is found to be

\[ F = |A|^2 (d^2 + 3) + 4 |B|^2 + 4 \Re (AB^*) \frac{d^2 + 1}{d}. \]  

(10)

Taking into account the normalization condition for the joint output state \( |\chi\rangle \),

\[ 2 (|A|^2 + |B|^2) (d^2 + 1) + 8d \Re (AB^*) = 1, \]  

(11)
we can maximize the fidelity, Eq. (10), which yields

\[ F = \frac{1}{4} \left( \frac{d^2 + 1}{d^2 - 1} + \frac{1}{d^2} \left( \frac{d^2 - 2}{d^2 - 1} \right)^2 \right). \]  (12)

Note that, for \( d = 2 \), this result coincides with the maximal fidelity of the entanglement cloner for two qubits obtained in [2], namely

\[ F = \frac{5 + \sqrt{13}}{12} \approx 0.7171. \]  (13)

The corresponding solution in \( d \) dimensions is

\[ A = \frac{d \sqrt{1 + Y(d)} - \sqrt{1 - Y(d)}}{2(d^2 - 1)}, \]  (14)

\[ B = \frac{-d \sqrt{1 - Y(d)} + \sqrt{1 + Y(d)}}{2(d^2 - 1)}, \]  (15)

where

\[ Y(d) = \left( 1 - \frac{(d^2 - 2)^2}{d^2(d^2 - 1)^2 + 4(d^2 - 2)^2} \right)^{1/2}. \]  (16)

IV. COMPARISON WITH OTHER CLONERS

We compare the fidelity achieved by our optimal \( d \times d \)-dimensional entanglement cloner, Eq. (12), with that of the universal cloner [3],

\[ F_u = \frac{1}{2} + \frac{1}{d^2 + 1}, \]  (17)

as well as that of the optimal real cloner [6]

\[ F_r = \frac{1}{2} + \frac{\sqrt{d^4 + 4d^2 + 20 - d^2 + 2}}{4(d^2 + 2)}. \]  (18)

In order to make this comparison consistent, we have obtained formulae (17) and (18) by replacing the argument \( d \) by \( d^2 \) in the original formulae. This is done because, in our consideration, the dimension \( d \) stands for the dimension of each component of the bipartite input state, so that the total dimension of our input state is \( d^2 \).

In Table I, we compare the fidelity \( F \) of our entanglement cloner with \( F_u \) and \( F_r \), for several values of the dimension \( d \). Our cloner performs better than the universal cloner in \( d^2 \) dimensions for all \( d \), which is obviously due to the fact that the ME states span only a subset of the entire set of \( d^2 \)-dimensional states. In contrast, the real \( d^2 \)-dimensional cloners outperform our cloners, except if \( d = 2 \) where they coincide [3]. This can be interpreted by noting that the set of \( d^2 \)-dimensional real states is generated by \( SO(d^2) \), with \((d^2 + 1)/2 - 1\) real degrees of freedom, while the set of ME states is generated by \( SU(d) \times SU(d) \), with \((d^2 - 1)^2\) real degrees of freedom. For \( d = 2 \), they coincide, so that our cloner provides the same fidelity as that of the real cloner in dimension 4, namely Eq. (13). This is related to the fact that the set of ME 2-qubit states is isomorphic to the set of 4-dimensional real states [3]. For \( d > 2 \), the set of ME states is in some sense “larger” than the set of real states for \( d > 2 \), so that the achievable fidelity of the entanglement cloner is lower. The fidelity of our cloner drops faster than that of the real cloner with increasing \( d \), but remains always higher than the fidelity of the universal cloner. As expected, in the limit \( d \to \infty \), all three fidelities tend to the asymptotic value 1/2. In this limit, all quantum cloners can be interpreted simply as a classical transformation that maps the original state to one of the clones, chosen at random, the other clone being prepared in a maximally mixed state.

Interestingly, we may also compare Eq. (12) to the fidelity of a “local cloner” obtained by applying a cloner separately to Alice’s and Bob’s components (see Fig. 1). Since the state of Alice’s or Bob’s subsystem is maximally mixed (hence non-polarized) when the bipartite state is ME, it is natural to use a universal \( d \)-dimensional cloner. We may observe that if we consider a cloning transformation that performs such a local universal cloning, then it is represented by a joint state of the same type as Eq. (11), see [3]. The only difference is that in the expression (11) for the tensor \( s_{ijkl} \), all coefficients must be equal, i.e., \( A = B = C = D \). The normalization condition (11) then gives immediately \( A = 1/(2(d + 1)) \). Substituting this expression into Eq. (10) results in the fidelity

\[ F_{loc} = \frac{1}{4} + \frac{d + 2}{2d(d + 1)} \]  (19)

for the local cloner. This fidelity is compared in Table 1 with that of the other cloners. It appears that cloning Alice’s and Bob’s parts locally leads to a much lower fidelity. Note that for \( d = 2 \), the value of the fidelity \( F_{loc} \) in Table 1 coincides with the value 7/12 obtained in [3]. In the limit \( d \to \infty \), this fidelity tends to 1/4, which can be easily understood in the classical picture above. To contribute to the fidelity, both cloners indeed need to map Alice’s and Bob’s components of the original state onto the right clone, which only happens with probability \((1/2)^2 = 1/4\).

| \( d \times d \) | \( F_r \) | \( F \) | \( F_u \) | \( F_{loc} \) |
|---|---|---|---|---|
| 2 \times 2 | 0.7171 | 0.7171 | 0.7000 | 0.5833 |
| 3 \times 3 | 0.6069 | 0.6019 | 0.6000 | 0.4583 |
| 4 \times 4 | 0.5617 | 0.5592 | 0.5588 | 0.4000 |
| 5 \times 5 | 0.5385 | 0.5386 | 0.5385 | 0.3667 |
| 6 \times 6 | 0.5277 | 0.5271 | 0.5270 | 0.3452 |

TABLE I: Optimal fidelity \( F \) of the \( d \times d \) entanglement cloner for various dimensions \( d \). It is compared to the fidelity of the real cloner \( F_r \) and universal cloner \( F_u \), both in \( d^2 \) dimensions, and to the fidelity of the \( d \times d \) “local” cloner \( F_{loc} \). The fidelities are shown in decreasing order.
V. ENTANGLEMENT OF FORMATION OF THE CLONES

In order to investigate the entanglement properties of our cloning transformation, we will use as an entanglement measure for the clones the entanglement of formation \( E \), which was computed for several classes of states that are invariant under some groups of local symmetries [8]. In particular, we will be interested in the class of states that are invariant under the transformations \( U \times U^* \) for all \( U \), called isotropic states in [3, 5]. These states may be written in a general form as

\[
\rho = \frac{1 - F}{d^2 - 1} (|\Phi\rangle\langle\Phi|) + F |\Phi\rangle\langle\Phi| \tag{20}
\]

where \( |\Phi\rangle \) is the identity and \( |\Phi\rangle \), which is simply given by Eq. (14). Due to the covariance condition [4], our QCM transforms isotropic states into states that are also invariant under \( U \times U^* \). We can check that, by cloning the particular ME state \( |\Phi\rangle \), which is \( U \times U^* \) invariant, we obtain a clone of the form

\[
\rho_a = \left( (d^2 + 2)|A|^2 + 2|B|^2 + 4d \Re(A^* B) \right) |\Phi\rangle \langle\Phi| + \left( |A|^2 + 2|B|^2 + \frac{4}{d} \Re(A^* B) \right) \mathbb{I} \tag{21}
\]

which is indeed an isotropic state and is consistent with Eq. (19). Hence, as a consequence of our covariance condition, all ME states, which can be obtained from \( |\Phi\rangle \) by applying local unitaries, are cloned onto isotropic states. For this class of states, the entanglement of formation is known for arbitrary dimensions [8, 10].

\[
E_F(\rho) = \begin{cases} 
0, & F \leq \frac{1}{d} \\
R_{1,d-1}(F), & F \in [\frac{1}{d}, \frac{4(d-1)}{d^2}] \\
d \frac{\log(d-1)}{2} (F - 1) + \log_2 d, & F \in [\frac{4(d-1)}{d^2}, 1]
\end{cases} \tag{22}
\]

where

\[
R_{1,d-1}(F) = H_2(\gamma(F)) + [1 - \gamma(F)] \log_2 (d-1), \tag{23}
\]

\[
\gamma(F) = \frac{1}{d} \left[ \sqrt{F} + \sqrt{(d-1)(1-F)} \right]^2, \tag{24}
\]

\[
H_2(p) = -p \log_2(p) - (1-p) \log_2(1-p). \tag{25}
\]

As shown in Fig. 2, the entanglement of formation \( E_F(\rho) \) is a monotonically increasing function of the fidelity \( F \) for isotropic states in any dimension \( d \). Therefore, by optimizing our QCM in terms of fidelity we maximize, at the same time, the entanglement of the clones measured by their entanglement of formation. The circles in Fig. 2 correspond to the maximal fidelity \( F \) that is achieved by our entanglement cloner, Eq. (22). They show as well the corresponding entanglement of formation in this dimension. The crosses mark the crossover between the expression of the fidelity corresponding to the second and third lines of Eq. (22). One notes that only for \( d \geq 7 \) there are values of the fidelity for which the entanglement of formation has to be evaluated according to the third line of Eq. (22).

In order to visualize how the entanglement itself is cloned, we plot in Fig. 3 the entanglement of formation \( E_F \) of the clones as a function of the entanglement of formation of the input ME state \( E_{in} \), which is simply the von Neumann entropy of the reduced density matrix \( E_{in} = \log_2 d \). We note that the entanglement of the clones is always less than one half the entanglement of the input state, while it asymptotically approaches this value for large \( d \). The apparent “discontinuity” (if one can say so for a discrete graph) corresponds to \( d = 7 \), i.e., the crossover between the second and the third line of Eq. (22) when calculating the entropy of formation. In the limit of \( d \to \infty \), the third line of Eq. (22) tends to \( E_F = F \log_2 d = F E_{in} \). Since the cloner can be viewed, in this limit, as a classical random distribution process associated with a fidelity \( F = 1/2 \), then the entanglement of each clone tends to one half the entanglement of the initial state.

In Fig. 3, we also plot the entanglement of formation resulting from the “local” cloner discussed above. Recall that this cloner differs from our optimal (non-local) entanglement cloner only by setting \( A = B \). Therefore it is also covariant, satisfying Eq. (3), and all our arguments about the entanglement of formation of the clones are applicable to this cloner as well. Thus, using the fidelity of the clones [19], we may plot the entanglement of formation of the clones. We see that the local cloner...
Alice’s component of the reference
clonetion for the state of the reference and the other
d the entanglement of the input state. The reason
the local (optimal cloner) behavior look more and more classical.

Increasing the dimensionality, we make the system be-
other states into separable states. First, an important obser-
Cimon is such that the input-to-single-
entanglement attainable by cloning is always below one half

In order to generalize this separability conservation
to all separable input states, outside the re-
stricted class of isotropic states, we consider the cloning
of a product state \( \rho_A \otimes \rho_B \). By tracing \((\rho_A \otimes \rho_B)^T S_{R,a} \)
over the reference \( R \), we obtain for the first clone a state of the form

\[
\rho_a = |A|^2 (1_A \otimes 1_B)_a \\
+ ((d^2 + 2)|A|^2 + 2|B|^2 + 4d \Re(A^* B)) (\rho_A \otimes \rho_B)_a \\
+ (d|B|^2 + 2 \Re(A^* B)) (\rho_A \otimes 1_B + 1_A \otimes \rho_B)_a
\]

where \( 1_A \) and \( 1_B \) are identities in Alice’s and Bob’s sub-
spaces of clone \( a \), respectively. Since all terms in (27)
are product states and all coefficients are positive semi-
definite for all \( d \), we verify that \( \rho_a \) is separable. By linear-
ity of the trace, this result also holds for any linear combi-
\( \sum_a p_i \rho_A^a \otimes \rho_B^a \) with \( p_i \geq 0 \) and \( \sum a p_i = 1 \), that is
for a generic separable state. Thus, we can conclude that
our entanglement cloner transforms all initially separable
states into separable clones.

VII. CONCLUSION

In conclusion, we have constructed an optimal (sym-
metric) entanglement cloner, which is universal over the
set of \( d \times d \) ME states in arbitrary dimension \( d \). On one
hand, all separable input states are cloned by this cloner
into separable states. In addition, the entanglement of
isotropic states cannot be increased by the cloner (and
we conjecture this property holds in general for any in-
put state). On the other hand, the entanglement of the
clones of ME input states is maximum. The optimiza-
tion of the parameters of our QCM was performed by
maximizing the fidelity of the clones, but the monotonic
behavior of the entanglement of formation as a function
of the fidelity for isotropic states guarantees that such an
optimization maximizes the entanglement of the clones at
the same time. We expect that entanglement is cloned
“monotonically” for all (including non-isotropic) states,
that is, higher entangled states result in higher entangled
clones, and therefore the ME input states are those which
generate the clones with the maximum achievable entan-
glement. If this very natural assumption is right, then,
based on our result, one can state that the maximal en-
taglement attainable by cloning is always below one half
of the entanglement of the input state and saturates this
value in the limit of large dimension \( d \). This is consistent
with the idea that, since our QCM transforms separable states into separable clones, no additional entanglement is produced by cloning, so we can only split the entanglement of the input state between the two clones. This explains as well the asymptotic value of one fourth the initial entanglement for the local cloner at the limit of large $d$. It is natural to expect all these conclusions to be valid for asymmetric entanglement cloners as well.
