Using data collected with the Belle detector at the KEKB asymmetric-energy $e^+e^-$ collider, we measure the energy dependence of the $e^+e^-\to h_0(nP)\pi^+\pi^-$ ($n = 1, 2$) cross sections from thresholds up to 11.02 GeV. We find clear $\Upsilon(10860)$ and $\Upsilon(11020)$ peaks with little or no continuum contribution. We study the resonant substructure of the $\Upsilon(11020)\to h_0(nP)\pi^+\pi^-$ transitions and find evidence that they proceed entirely via the intermediate isovector states $Z_{b}(10610)$ and $Z_{b}(10650)$. The relative fraction of these states is loosely constrained by the current data: the hypothesis that only $Z_{b}(10610)$ is produced is excluded at the level of 3.3 standard deviations, while the hypothesis that only $Z_{b}(10650)$ is produced is not excluded at a significant level.

PACS numbers: 14.40.Rt, 14.40.Pq, 13.66.Bc

Heavy quarkonium is a bound state of the $c\bar{c}$ or $b\bar{b}$ quarks. The heavy quarks are moving relatively slowly; therefore, a non-relativistic approximation based on the interaction potential accurately describes the basic properties of this system. The first state that did not fit potential model expectations was observed in 2003 by Belle; since then, almost twenty such states have been reported. They correspond to high excitations and...
have masses above the $D\bar{D}$ or $B\bar{B}$ thresholds.

Many charmonium-like states were found in the energy scans of the cross sections of $e^+e^-$ annihilation into conventional quarkonia and light hadrons. Among these are the $Y(4008)$ and $Y(4260)$ in $J/\psi \pi^{-}\pi^{-}$, the $Y(4360)$ and $Y(4660)$ in $\psi(2S) \pi^+\pi^-$, the $\psi(4040)$ and $\psi(4160)$ in $J/\psi \eta$, and possibly the $Y(4220)$ in $h_c \pi^+\pi^-$. The partial widths of the corresponding transitions are much higher than expected for conventional quarkonia. Surprisingly, the peaks observed in the cross sections depend on the final states. In other words, each such charmonium-like state decays to only one channel with charmonium. To explain this "selectivity", a hadrocharmonium notion is introduced: a bound state of a charmonium-like state decays to only one channel with charmonium. To explain this "selectivity", a hadrocharmonium-like state decays to only one channel with charmonium-like states. Hereinafter, the $Y(5S)$ and $Y(6S)$ according to the potential model calculation up to the second order, and take into account the probability density of the initial state radiation ground develops a dip slightly above the center-of-mass (c.m.) energy and $E_{c.m.}$ and $p_{c.m.}^\perp$ are the energy and momentum of the $\pi^+\pi^-$ pair as measured in the c.m. frame. The c.m. energy is calibrated using the $e^+e^-\rightarrow \Upsilon(nS)\pi^+\pi^-$ process, as described in Ref. [11]. This analysis closely follows previous Belle publications [13, 14, 18].

We use a general hadronic event selection with requirements on the position of the primary vertex, track multiplicity, and the total energy and momentum of the event. These criteria suppress Bhabha, $\mu^+\mu^-$, $\pi^+\pi^-$, two-photon and beam–gas processes. Continuum $e^+e^-\rightarrow q\bar{q}$ ($q = u, d, s, c$) events have jet-like shapes in contrast to the spherically symmetric signal events and are suppressed by a requirement on the ratio of the second to zeroth Fox-Wolfram moments: $R_2 < 0.3$ [20]. We only consider positively identified $\pi^+\pi^-$ candidates that originate from the interaction point region. The measurements of the cross sections are performed with an additional requirement on the single-pion $\pi^\pm$ missing mass,

$$10.59 \text{ GeV}/c^2 < M_{\text{miss}}(\pi^\pm) < 10.67 \text{ GeV}/c^2,$$

which selects signal events proceeding via the intermediate $Z_b(10610)$ or $Z_b(10650)$ states. We combine the $M_{\text{miss}}(\pi\pi)$ distribution for $\pi^+$ satisfying (11) and that for $\pi^-$ satisfying (11). The $\pi^+\pi^-$ pairs with both $M_{\text{miss}}(\pi^+)$ and $M_{\text{miss}}(\pi^-)$ in the $Z_b$ mass window are counted twice. (If they are counted only once, the combinatorial background develops a dip slightly above the $h_b(2P)$ signal, making the background parameterization difficult.) We take the double entries into account by correcting the errors of the $M_{\text{miss}}(\pi\pi)$ histogram and, based on Monte Carlo (MC) simulation, the $h_b(2P)$ signal yields.

We fit the $M_{\text{miss}}(\pi\pi)$ distribution in the $h_b(1P)$ and $h_b(2P)$ intervals, defined as $9.8 \text{ GeV}/c^2 - 10.0 \text{ GeV}/c^2$ and $10.17 \text{ GeV}/c^2 - 10.34 \text{ GeV}/c^2$, respectively. The fit function is the sum of the $h_b(nP)$ signal and combinatorial- and peaking-background components. The shapes of the $h_b(nP)$ signals are determined by convolving the probability density of the initial state radiation (ISR) process with the experimental resolution, described by a Gaussian. We use the ISR probability, calculated up to the second order [21], and take into account the energy dependence of the $e^+e^-\rightarrow h_b(nP)\pi^+\pi^-$ cross sections using an iterative procedure. The resolution is determined using the exclusively reconstructed decays $\Upsilon(5S)\rightarrow \Upsilon(nS)\pi^+\pi^-$, $\Upsilon(nS)\rightarrow \mu^+\mu^-$ to be $(6.84 \pm 0.13) \text{ MeV}/c^2$ for the $h_b(1P)$ and $(6.15 \pm 0.22) \text{ MeV}/c^2$ for the $h_b(2P)$. The resolution is dominated by c.m. energy smearing. The $h_b(nP)$ masses are fixed at the previous Belle measurement [18]. We normalize the signal density functions in such a way that the measured $h_b(nP)$ yields include the ISR correction, $1 + \delta_{\text{ISR}}$, and can be used directly to measure the Born cross sections. The combinatorial background is described by a fourth-order
Chebyshev polynomial in both fit intervals. The order is chosen by maximizing the confidence level of the fit.

Using MC simulation, we find that combining a random pion that satisfies the $Z_b$ mass requirement and a signal pion from $Z_b \rightarrow h_b(nP)\pi$ produces a broad bump under the $h_b(nP)$ signal. This background is incorporated within the combinatorial background and results in minor corrections in the $h_b(1P)$ and $h_b(2P)$ yields of 0.99 ± 0.01 and 0.995 ± 0.005, respectively. The $\pi^+\pi^-$ pairs originating from the $Y(2S) \rightarrow Y(1S)\pi^+\pi^-$ transitions with the $Y(2S)$ produced inclusively or via ISR result in a peak at $E_{c.m.} - (m_{Y(2S)} - m_{Y(1S)})$ that is inside the $h_b(2P)$ fit interval for the c.m. energies close to the $Y(5S)$. The shape of this peaking background is found to be a Gaussian with $\sigma = 11$ MeV/$c^2$. Its normalization is floated in the fit.

To determine the reconstruction efficiency, we use phase-space-generated MC, weighted in $M_{\text{miss}}(\pi\pi)$ according to the fit results for the $Y(5S) \rightarrow h_b(1P)\pi^+\pi^-$ transition [14] and in angular variables according to the expectations for the $Z_b$ spin-parity $J^P = 1^+$ [22]. The efficiencies for the $h_b(1P)\pi^+\pi^-$ and $h_b(2P)\pi^+\pi^-$ channels are in the range 40–55% and 35–50%, respectively; they rise with c.m. energy. At the lowest energy point, there is a drop of efficiency by a factor of two since this point is close to the kinematic boundary and the pion momenta are low.

At each energy, the Born cross section is determined according to the formula:

$$\sigma^B(e^+e^- \rightarrow h_b(nP)\pi^+\pi^-) = \frac{N}{L \varepsilon |1 - \Pi|^2},$$

where $N$ is the number of signal events determined from the $M_{\text{miss}}(\pi\pi)$ fit that includes the ISR correction, $L$ is the integrated luminosity, $\varepsilon$ is the reconstruction efficiency and $|1 - \Pi|^2$ is the vacuum polarization correction [22], which is in the range 0.927 – 0.930. The resulting cross sections are shown in Fig. 1. The cross sections, averaged over the three high statistics on-resonance points at $E_{c.m.} = (10865.6 \pm 2.0)$ MeV, are

$$\sigma^B(e^+e^- \rightarrow h_b(1P)\pi^+\pi^-) = 1.66 \pm 0.09 \pm 0.10 \text{ pb},$$

(3)

$$\sigma^B(e^+e^- \rightarrow h_b(2P)\pi^+\pi^-) = 2.70 \pm 0.17 \pm 0.19 \text{ pb}.$$  

(4)

The ratio of the cross sections is 0.616 ± 0.052 ± 0.017. Here and elsewhere in this Letter, the first uncertainties are statistical and the second are systematic.

The systematic uncertainties in the signal yields originate from the signal and background shapes. The relative uncertainty due to the $M_{\text{miss}}(\pi\pi)$ resolution is correlated among different energy points and is equal to 1.4% for the $h_b(1P)$ and 3.3% for the $h_b(2P)$. The uncertainties due to the $h_b(nP)$ masses and ISR tail shapes are found to be negligible. To estimate the background-shape contribution, we vary the fit interval limits by about 50 MeV and the polynomial order for each fit interval. The corresponding uncertainties are considered uncorrelated and are 1.1% and 2.5% for the on-resonance cross sections in Eqs. 3 and 4, respectively.

A relative uncertainty in the efficiency contributes to the correlated systematic uncertainty. An uncertainty due to the $Z_b$ mass requirement of $\pm 1.0\%$ is estimated by varying the $Z_b$ parameters by $\pm 1\sigma$ and taking into account correlations among different parameters. The efficiency of the $R_2$ requirement is studied using inclusively reconstructed $Y(5S) \rightarrow Y(nS)\pi^+\pi^-$ decays. We find good agreement between data and MC and assign the 5% statistical uncertainty in data as a systematic uncertainty due to the $R_2$ requirement. Finally, we assign a 1% uncertainty per track due to possible differences in the reconstruction efficiency between data and MC.

An uncertainty in the luminosity of 1.4% is primarily due to the simulation of Bhabha scattering that is used for its determination and is correlated among energy points. We add in quadrature all the contributions to find the total systematic uncertainties shown in Eqs. 3 and 4. The values of the cross sections for all energy points are provided in Ref. 24.

The shapes of the $h_b(1P)\pi^+\pi^-$ and $h_b(2P)\pi^+\pi^-$ cross sections look very similar. They show clear $Y(5S)$ and $Y(6S)$ peaks without significant continuum contributions. We perform a simultaneous fit of the shapes,
Adding in quadrature the statistical and uncorrelated systematic uncertainties at each energy point. We use the coherent sum of two Breit-Wigner amplitudes:

\[ A_n \Phi_n(s) | F_{BW}(s, M_5, \Gamma_5) + a \, e^{i \phi} F_{BW}(s, M_6, \Gamma_6) |^2, \quad (5) \]

where \( s = E_{c.m.}^2 \), \( \Phi_n(s) \) is the phase space calculated numerically, taking into account the measured \( Z_b \) line shape \([14]\), and \( F_{BW}(s, M, \Gamma) = M \Gamma / (s - M^2 + iM \Gamma) \) is a Breit-Wigner amplitude. The fit parameters \( M_5, \Gamma_5, M_6, \Gamma_6, a, \) and \( \phi \) are common for the two channels, while only the normalization coefficients \( \Lambda_n \) are different. Equation (5) is convolved with the \( E_{c.m.} \) resolution of \((5.0 \pm 0.4) \text{ MeV}\), which is found using exclusively reconstructed \( \Upsilon(5S) \rightarrow \Upsilon(nS)\pi^+\pi^- \) events. The fitted functions are shown in Fig. 1. The confidence level of the fit is 93%. The fit results are:

\[
M_5 = (10884.7^{+3.6}_{-3.4} \pm 1.0) \text{ MeV/c}^2, \quad (6)
\]

\[
\Gamma_5 = (40.6^{+12.7}_{-8.0} \pm 1.1) \text{ MeV}, \quad (7)
\]

\[
M_6 = (10999.0^{+7.3}_{-7.8} \pm 1.6) \text{ MeV/c}^2, \quad (8)
\]

\[
\Gamma_6 = (27^{+27}_{-11} \pm 2) \text{ MeV}, \quad (9)
\]

\[
a = 0.65^{+0.36}_{-0.12} \pm 0.17 \quad \text{and} \quad \phi = (0.1^{+0.4}_{-0.8} \pm 0.3) \pi. \quad (10)
\]

The measured masses and widths agree with the results of the \( \Upsilon(nS)\pi^+\pi^- \) scan \([11]\).

The first error in the fit results is not purely statistical but includes uncorrelated systematic uncertainties in the cross sections. The contributions of other considered sources are listed in Table I.

| Fit model | \( M_5 \) | \( \Gamma_5 \) | \( M_6 \) | \( \Gamma_6 \) | \( a \) | \( \phi \) |
|-----------|---------|---------|---------|---------|-------|-------|
| \( Z_b \) substructure | \(+8.9\) | \(+0.4\) | \(+16.7\) | \(+0.0\) | \(+0.12\) | \(+0.09\) |
| \( Z_b \) substructure | \(+0.2\) | \(+0.0\) | \(+0.1\) | \(+0.7\) | \(+0.11\) | \(+0.00\) |
| \( Z_b \) substructure | \(-0.0\) | \(-0.0\) | \(-0.0\) | \(-0.0\) | \(-0.0\) | \(-0.0\) |
| \( \sqrt{s} \) scale | \(+1.0\) | \(+0.0\) | \(+0.0\) | \(+0.0\) | \(+0.0\) | \(+0.0\) |
| Resolution | \(+0.0\) | \(+0.0\) | \(+0.0\) | \(+0.0\) | \(+0.0\) | \(+0.0\) |
| Total | \(+8.9\) | \(+1.4\) | \(+16.9\) | \(+0.4\) | \(+0.17\) | \(+0.27\) |

\( | \Phi_\mu \rangle | F_{BW}(s, M_5, \Gamma_5) \rangle |^2 = \langle \Phi_\mu | F_{BW}(s, M_6, \Gamma_6) \rangle |^2, \quad (5) \]

where \( s = E_{c.m.}^2 \), \( \Phi_\mu(s) \) is the phase space calculated numerically, taking into account the measured \( Z_b \) line shape \([14]\), and \( F_{BW}(s, M, \Gamma) = M \Gamma / (s - M^2 + iM \Gamma) \) is a Breit-Wigner amplitude. The fit parameters \( M_5, \Gamma_5, M_6, \Gamma_6, a, \) and \( \phi \) are common for the two channels, while only the normalization coefficients \( \Lambda_n \) are different. Equation (5) is convolved with the \( E_{c.m.} \) resolution of \((5.0 \pm 0.4) \text{ MeV}\), which is found using exclusively reconstructed \( \Upsilon(5S) \rightarrow \Upsilon(nS)\pi^+\pi^- \) events. The fitted functions are shown in Fig. 1. The confidence level of the fit is 93%. The fit results are:

\[
M_5 = (10884.7^{+3.6}_{-3.4} \pm 1.0) \text{ MeV/c}^2, \quad (6)
\]

\[
\Gamma_5 = (40.6^{+12.7}_{-8.0} \pm 1.1) \text{ MeV}, \quad (7)
\]

\[
M_6 = (10999.0^{+7.3}_{-7.8} \pm 1.6) \text{ MeV/c}^2, \quad (8)
\]

\[
\Gamma_6 = (27^{+27}_{-11} \pm 2) \text{ MeV}, \quad (9)
\]

\[
a = 0.65^{+0.36}_{-0.12} \pm 0.17 \quad \text{and} \quad \phi = (0.1^{+0.4}_{-0.8} \pm 0.3) \pi. \quad (10)
\]

The measured masses and widths agree with the results of the \( \Upsilon(nS)\pi^+\pi^- \) scan \([11]\).

The first error in the fit results is not purely statistical but includes uncorrelated systematic uncertainties in the cross sections. The contributions of other considered sources are listed in Table I.

To study systematic uncertainties due to the fit model, we introduce a non-resonant continuum amplitude, \( b \, e^{i \delta} \).

The significance of this contribution is only 1.6\( \sigma \). However, the shifts in the fit results are large, and this is the dominant source of systematic uncertainty. We also consider the possibility that the parameters \( a \) and \( \phi \) are different in the \( h_b(1P)\pi^+\pi^- \) and \( h_b(2P)\pi^+\pi^- \) channels. We find that the values in the two channels agree and the shifts in masses and widths are small. Using MC pseudo-experiments, we find that there is no significant fit bias.

If the resonant substructures of the \( \Upsilon(5S) \) and \( \Upsilon(6S) \) decays are different, the \( \Upsilon(5S) \) and \( \Upsilon(6S) \) amplitudes in \([5]\) are not fully coherent, and the interference term is suppressed by a decoherence factor \( k \) \([11]\). If only \( Z_b(10610) \) is produced at the \( \Upsilon(6S) \), \( k \) is calculated numerically to be 0.62; if only \( Z_b(10650) \) is produced, \( k \) is 0.80. We introduce these factors in the fit and take into account that the efficiency of the \( Z_b \) mass requirement is smaller for a single \( Z_b \) state compared to two \( Z_b \) states by 12% since the two \( Z_b \) states interfere destructively outside their signal region.

We account for an uncertainty in the \( E_{c.m.} \) scale and the uncertainty in the \( E_{c.m.} \) resolution. We add in quadrature the contributions of the various sources to determine the total systematic uncertainties.

To study the resonant substructure of the \( \Upsilon(6S) \rightarrow h_b(nP)\pi^+\pi^- \) transitions, we combine the data samples of the five highest-energy points. The fits to the corresponding \( \sigma_{\text{miss}}(\pi\pi) \) spectra in the \( h_b(1P) \) and \( h_b(2P) \) intervals are shown in Figs. 2 and 3. The \( h_b(nP) \) signals are determined by averaging over the data samples that are combined; we use weights proportional to the integrated luminosity and the cross section at each energy. The confidence levels of the fits are 50% and 52%, respectively. From Wilks’ theorem \([25]\), we find that the significances of the \( h_b(1P) \) and \( h_b(2P) \) signals are 3.5\( \sigma \) and 5.3\( \sigma \), respectively, including systematic uncertainty, determined by varying the polynomial order. Thus, we find the first evidence for the \( \Upsilon(6S) \rightarrow h_b(1P)\pi^+\pi^- \) transition and observe for the first time the \( \Upsilon(6S) \rightarrow h_b(2P)\pi^+\pi^- \) transition.

We release the requirement of an intermediate \( Z_b \) and
fit the \( M_{\text{miss}}(\pi\pi) \) spectra in bins of \( M_{\text{miss}}(\pi) \) to measure the \( h_b(nP)\pi^+\pi^- \) yields as functions of \( M_{\text{miss}}(\pi) \). The distribution of the phase-space-generated signal events in the \( M_{\text{miss}}(\pi^+) \) vs. \( M_{\text{miss}}(\pi^-) \) plane has the shape of a narrow slanted band; each structure at high values of \( M_{\text{miss}}(\pi^+) \) produces a “reflection” at small values of \( M_{\text{miss}}(\pi^-) \). We combine the \( M_{\text{miss}}(\pi\pi) \) spectra for the corresponding \( M_{\text{miss}}(\pi^+) \) and \( M_{\text{miss}}(\pi^-) \) bins and consider the upper half of the available \( M_{\text{miss}}(\pi) \) range. Thereby, we consider all signal events and avoid double counting. The yields, corrected for the reconstruction efficiencies, are shown in Fig. 4. The data are not distributed uniformly in phase space; they populate the \( Z_0(10610) \) and \( Z_b(10650) \) mass region. We fit the data to a shape where the \( Z_0(10610) \) and \( Z_b(10650) \) parameters are fixed to the \( \Upsilon(5S) \rightarrow Z_0\pi \rightarrow h_b(1P)\pi^+\pi^- \) result and the non-resonant contribution is set to zero [14]. Such a model describes the data well: the confidence levels of the fits are 65% and 77% for the \( h_b(1P) \) and \( h_b(2P) \), respectively. The phase space hypothesis is excluded relative to this model at the 3.6\( \sigma \) and 4.5\( \sigma \) levels in the \( h_b(1P)\pi^+\pi^- \) and \( h_b(2P)\pi^+\pi^- \) channels, respectively. The single \( Z_0(10610) \) hypothesis is excluded at the 3.3\( \sigma \) level in the \( h_b(1P)\pi^+\pi^- \) channel, while the single \( Z_0(10650) \) hypothesis cannot be excluded at a significant level. In the \( h_b(2P)\pi^+\pi^- \) channel, the \( Z_0(10610)^\pm \) and \( Z_b(10650)^\pm \) signals overlap with the \( Z_0(10650)^\mp \) and \( Z_b(10610)^\mp \) reflections, respectively, which obscures the determination of the relative yields. The exclusion levels are determined using pseudo-experiments from the \( \chi^2 \) differences of the two hypotheses being compared, and include systematic uncertainty.

In conclusion, we have measured the energy dependence of the \( e^+e^- \rightarrow h_b(nP)\pi^+\pi^- \, (n = 1, 2) \) cross sections. We find two peaks corresponding to the \( \Upsilon(5S) \) and \( \Upsilon(6S) \) states and measure their parameters, which agree with the results from Ref. [11]. The data are consistent with no continuum contribution.

We report first evidence for \( \Upsilon(6S) \rightarrow h_b(1P)\pi^+\pi^- \) and first observation of the \( \Upsilon(6S) \rightarrow h_b(2P)\pi^+\pi^- \) transitions. We study their resonant substructures and find evidence that they proceed entirely via the intermediate isovector states \( Z_0(10610) \) and \( Z_b(10650) \). Their relative fraction is loosely constrained by the current data: the hypothesis that only \( Z_0(10610) \) is produced is excluded at the 3.3\( \sigma \) level, while the hypothesis that only \( Z_b(10650) \) is produced is not excluded at a significant level.

The shapes of the \( e^+e^- \rightarrow h_b(nP)\pi^+\pi^- \) and \( e^+e^- \rightarrow \Upsilon(nS)\pi^+\pi^- \) cross sections look similar. The only significant difference is a smaller relative yield of \( \Upsilon(nS)\pi^+\pi^- \) at the \( \Upsilon(6S) \). Since the \( h_b(nP)\pi^+\pi^- \) final states are produced only via intermediate \( Z_b \) while \( \Upsilon(nS)\pi^+\pi^- \) at the \( \Upsilon(5S) \) are produced both via \( Z_0 \) and non-resonantly, this difference indicates that the non-resonant contributions in \( \Upsilon(nS)\pi^+\pi^- \) are suppressed at the \( \Upsilon(6S) \).

We thank the KEKB group for excellent operation of the accelerator; the KEK cryogenics group for efficient solenoid operations; and the KEK computer group, the NII, and PNRL/EMSL for valuable computing and SINET4 network support. We acknowledge support from MEXT, JSPS and Nagoya’s TLPRC (Japan); ARC (Australia); FWF (Austria); NSFC and CCEPP (China); MSMT (Czechia); CZF, DFG, EXC153, and VS (Germany); DST (India); INFN (Italy); MOE, MSIP, NRF, BK21Plus, WCU and RSRI (Korea); MNiSW and NCN (Poland); MES, RFAAE and RSF under Grant No. 15-12-30014 (Russia); ARRS (Slovenia); IKERBASQUE and UPV/EHU (Spain); SNSF (Switzerland); MOE and MOST (Taiwan); and DOE and NSF (USA).
