(October 29, 2018)

We investigate broken rotational symmetry (BRS) states at half-filling of the valence Landau level (LL). We generalize Rezayi-Read’s (RR) composite fermion (CF) trial wavefunctions to include anisotropic coupling of the flux quanta to electrons, thus generating a nematic order in the underlying CF liquid. Using the Fermi hypernetted-chain (FHNC) method which readily gives results in the thermodynamic limit, we determine in detail the properties of these states. By using the anisotropic pair distribution and static structure functions we determine the correlation energy and find that, as expected, RR’s state is stable in the lowest LL, whereas BRS states may occur at half-filling of higher LLs, with possible connection to the recently discovered quantum Hall liquid crystals.

I. INTRODUCTION

During the past two decades the physics of two-dimensional electron systems (2DES) has provided some of the richest grounds for new developments in condensed matter physics. In particular the integer [3] and fractional [4] quantum Hall effects (QH) in strong magnetic fields are some of the most remarkable phenomena discovered in the second half of the XX Century and rival superconductivity in their fundamental significance by manifesting quantum mechanics on macroscopic scales and providing a major impetus to the development of new ideas in many-body physics [5], like the existence of fractionally charged quasiparticles [6], topological quantum numbers [7], chiral Luttinger liquids [8], composite particles [9], etc. One of the reasons that 2DES keep supplying novel and exciting results is the improved quality of the samples with mobilities increasing roughly exponentially with time, thus allowing the emergence of new, subtler effects due to electronic correlations (which are enhanced because of the reduced dimensionality).

Consider initially a 2DES at half-filling ($\nu = 1/2$) of the lowest Landau level (LLL). Experimentally, this state does not exhibit the typical features of the fractional quantum Hall effect (FQHE), namely the very precise quantization of the transverse conductance in units of quantum Hall effect (FQHE), namely the very precise quantization of the transverse conductance in units of $e^2/h$, or the vanishing longitudinal resistivity. Yet, the resistivity shows a broad minimum [8], and anomalous behavior in the propagation of surface acoustic waves [9] has been observed. Early numerical work by Halperin, Lee, and Read (HLR) [10-12] suggested that $\nu = 1/2$ is not incompressible. The overall experimental evidence strongly suggests that, in the LLL, for half-filling the system behaves like a strange Fermi liquid at close to zero effective magnetic field [$^{11,13}$].

A theory of compressible Fermi-liquid-like behavior at half filling has been proposed by Halperin, Lee, and Read (HLR) [14]: a two-dimensional (2D) system of electrons subjected to an external perpendicular magnetic field, at half filling of the LLL can be transformed to a mathematically equivalent system of fermions interacting with a Chern-Simons gauge field such that the average effective magnetic field acting on the fermions is zero [$^{14}$]. Since these fermions do not see a net magnetic field, they can form a 2D Fermi sea of uniform density. In a very successful approach, based on the composite fermion (CF) theory [6,13], Rezayi-Read [$^{16}$] (RR) described the half-filled state by a correlated Fermi wave function that is a product of a Slater determinant of plane waves with a Jastrow factor corresponding to a Bose Laughlin state at half filling:

$$\Psi(r_1, \ldots, r_N) = \hat{P}_0 \prod_{j<k} (z_j - z_k)^2 e^{-\sum_{k=1}^{N} |z_k|^2/4} \det |\varphi_k(r_i)|,$$

where $\varphi_k(r_i)$ are 2D plane waves for fully spin polarized CF states that fill a 2D disk in reciprocal space with Fermi momentum $k_F$, $z_j = x_j + i y_j$ is the complex 2D coordinate of $j$-th electron and $\hat{P}_0$ is a projector onto the LLL ($L = 0$). We work in units of the magnetic length ($l_B^2 = h/eB = 1$).

The situation is dramatically different for the next LL (LL index $L = 1$), where for $\nu \simeq 5/2$ a quantized Hall conductance is observed along with a strong reduction of the longitudinal conductance [$^{17}$], which are an indication of a Cooper pairing instability of the CFs [$^{13}$]. A discussion of this state is a wide and complex topic by itself and this, along with the properties of the $\nu = 3/2$ and $7/2$ states (half filling of the upper spin sub-band) will not be addressed in this work.

In this paper we discuss some aspects related to the many interesting new phenomena that have recently emerged in nearly half-filled higher LLs (with LL index $L \geq 2$), in particular the extreme anisotropy measured in the low temperature magnetotransport [19,20]. This anisotropic behavior has been attributed to the formation of a nematic phase of the 2DES which, at higher temperatures undergoes a nematic to isotropic transition [$^{22,23}$]. The motivation of our work is to study these nematic...
II. BASIC THEORY

In this work we study the stability of different states by using trial wavefunctions of the form of Eq. (3). We perform this analysis by comparing the energy in each of these states to find the optimum value for the anisotropy-generating parameter $\alpha$. The potential, or correlation energy per electron is given by:

$$E_\alpha = \frac{1}{N} \frac{\langle \Psi_\alpha | \hat{V} | \Psi_\alpha \rangle}{\langle \Psi_\alpha | \Psi_\alpha \rangle} = \frac{\rho}{2} \int d^2r \, V(r) \, [g(r) - 1] \, , \quad (3)$$

where $\hat{V}$ represents the electron-electron, electron-background, and background-background interaction; and $g(r)$ is the (angle-dependent) pair distribution function given by

$$g(r) = \frac{N(N-1)}{\rho^2} \int d^2r_3 \cdots d^2r_N |\Psi_\alpha(r_1 \cdots r_N)|^2 \, , \quad (4)$$

where $r = r_2 - r_1$. The following normalization condition, $\rho \int d^2r \, [g(r) - 1] = -1$, can be used as a convenient check for numerical procedures. For an ideal 2D sample the interaction is a pure Coulomb potential $V(r) \simeq e^2/(er)$, while in samples with finite thickness a reasonable choice is the Zhang Das Sarma (ZDS) potential $V(r) = e^2/(\epsilon \sqrt{r^2 + \lambda^2})$, where $\lambda$ is of the order of the sample thickness. Alternatively, the correlation energy can be computed in reciprocal space:

$$E_\alpha = \frac{1}{2} \int \frac{d^2q}{(2\pi)^2} \bar{V}(q) \, |S(q) - 1| \, , \quad (5)$$

where $\bar{V}(q)$ is the 2D Fourier transform (FT) of $V(r)$ and $S(q)$ is the static structure factor:

$$S(q) - 1 = \rho \, \text{FT}[g(r) - 1] \, . \quad (6)$$

While both $g(r)$ and $S(q)$ are angle-dependent (e.g. see Figs. 3 and 3), because the interaction potential is centrally symmetric, the energy $E_\alpha$ depends only on the angle-averaged pair distribution function or static structure factor defined as:

$$g(r) = \int_0^{2\pi} \frac{d\theta}{2\pi} \, g(r) \, , \quad \mathbf{S}(q) = \int_0^{2\pi} \frac{d\theta}{2\pi} \, S(q) \, . \quad (7)$$

The determination of either the pair distribution function or the structure factor is generally a complicated integral problem that needs to be solved for each LL. However, its is known that if transitions to other LLs are neglected (i.e. a single-LL approximation), $g(r)$ and $S(q)$ at higher LLs are simply related to those at the LLL ($L = 0$) by means of a convolution or product respectively. We will apply this approximation (which, moreover, quenches the kinetic energy in higher LLs as well).
It is then, sufficient to compute these distribution functions once in the LLL and then the correlation energy per electron is given by

$$E_a^L = \frac{1}{2} \int \frac{d^2q}{(2\pi)^2} \tilde{V}_{\text{eff}}(q) \left[ S(q) - 1 \right],$$

(8)

where $\tilde{V}_{\text{eff}}(q) \equiv \tilde{V}(q) [L_L(q^2/2)]^2$. $L_L(z)$ are Laguerre polynomials, and $S(q)$ is calculated in the LLL ($L = 0$).

In what follows we compute $g(\mathbf{r})$ and $S(q)$ using the FHNC method.

### III. THE FERMI HNC METHOD FOR THE BROKEN ROTATIONAL SYMMETRY STATE

The development of the FHNC method for Fermi systems \cite{cite1, cite2} allows one to estimate accurately the expectation value of a Hamiltonian, the pair distribution function and related quantities associated with a Jastrow-Slater wave function and other more complex many-body Fermi wave functions. The FHNC method treats the correlated system of particles a priori in the thermodynamic limit therefore is extremely useful on the study of infinite homogeneous Fermi systems described by correlated Fermi wave functions, having (but not limited to) a Jastrow-Slater form. In addition one can prove that the FHNC scheme achieves convergence of the expectation value of a Hamiltonian within some expansion scheme \cite{cite3} thus substantiating the belief that FHNC gives an accurate upper bound for the energy and other related quantities \cite{cite4, cite5}.

An important problem arises at this stage. The projection onto the $L$\textsuperscript{th} LL performed in the RR wavefunction or its generalization \cite{cite6} leads to a wavefunction that cannot be directly treated within the FHNC formalism, because the simple Jastrow $\times$ Slater determinant structure of single particle orbitals is lost. We therefore use an unprojected version of Eq. \cite{cite7}, which although approximate, is believed to contain the most important physics, especially since the Jastrow factors already significantly annihilate higher-LL components of the wavefunction \cite{cite8}. In addition, although the wave function given in Eq. \cite{cite9} has a Jastrow-Slater form after dropping the projector $P_L$, the FHNC method in this case differs from the standard approach since two-body correlation factors and related quantities depend not only on inter-particle distance, but also on the relative angle between the particles. In order to calculate the pair distribution function the modulus square of the wave function:

$$|\Psi_\alpha(\mathbf{r}_1, \ldots, \mathbf{r}_N)|^2 = e^{\sum_{i<j}^N u(z_i - z_j)} \times e^{-\sum_{i=1}^N \frac{|z_i|^2}{2} |\det [\varphi_k(\mathbf{r}_i)]|^2},$$

(9)

where $u(z) = \ln |z - \alpha|^2 + \ln |z + \alpha|^2$, is expanded perturbatively in terms of $h(\mathbf{r}_{ij}) = \exp[u(\mathbf{r}_{ij})] - 1$ and may be ordered as:

$$|\Psi_\alpha|^2 = \left[ 1 + \sum_{i<j}^N h(\mathbf{r}_{ij}) + \sum_{i<j}^N \sum_{k<l}^N h(\mathbf{r}_{ij}) h(\mathbf{r}_{kl}) + \cdots \right] \times |\det [\varphi_k(\mathbf{r}_i)]|^2.$$  

(10)

In addition to dynamical correlations between particles, described by the pseudopotential $u(z_i - z_j)$, there are also statistical correlations described by the Slater determinant which renders the whole state antisymmetric. Similar to the Jastrow part, we may expand $|\det [\varphi_k(\mathbf{r}_i)]|^2$ in the number of exchanges between particles. In this way Eq. \cite{cite10} becomes a quite symmetrical expansion in the number of dynamical correlation factors, $h(\mathbf{r}_{ij})$, as well as the number of statistical correlation factors. The resulting cluster terms in the expression for $g(\mathbf{r}_{12})$ contain both kinds of correlations and may be represented by cluster diagrams. As in the Bose case, the associated pair distribution function $g(\mathbf{r}_{12})$ is then given by the sum of all linked irreducible diagrams obeying well-defined topological rules \cite{cite11}.

One defines nodal, composite (non-nodal), and elementary diagrams as in the Bose case, but there are now four different types for each of them. The four different classes of nodal, composite and elementary diagrams are generally denoted by $dd$ (direct-direct), $de$ (direct-exchange), $ee$ (exchange-exchange), and $cc$ (circular-exchange). Then the pair distribution function is obtained from the set of FHNC equations given in the Appendix, where $\rho$ is the density, $g_s(= 1)$ is the spin degeneracy and $l(\mathbf{r}_{12})$ is the familiar statistical exchange factor for the 2D Slater determinant given by

$$l(\mathbf{r}_1, \mathbf{r}_2) = \frac{2 J_1(k_F r_{12})}{k_F r_{12}},$$

(11)

where $r_{12} = |\mathbf{r}_2 - \mathbf{r}_1|$ and $J_1(x)$ is the first order Bessel function.

For standard systems like the $^3$He Fermi liquid, the pair correlation factor is short-range and heals to 1 for large distances, therefore the function $\exp[u(\mathbf{r}_{ij})] - 1$ provides a possible expansion parameter [note that in order to apply the Fermi HNC expansion, the correlation (pseudo) potential has to satisfy the conditions: $u(\mathbf{r}_{ij} \to 0) \to -\infty$ and $u(\mathbf{r}_{ij} \to +\infty) \to 0$]. In the case of the BRS wave function, the (pseudo) potential $u(\mathbf{r})$ is logarithmically long-range, however formally it is possible to extend the method by splitting the pseudopotential associated with the Jastrow part into a short- and a long-range part, respectively,

$$u(\mathbf{r}_{12}) = u_s(\mathbf{r}_{12}) + u_l(\mathbf{r}_{12}),$$

(12)

with the $dd$ nodal and composite function similarly split:

$$N_{dd}(\mathbf{r}_{12}) = N_{dds}(\mathbf{r}_{12}) - u_l(\mathbf{r}_{12}),$$

(13)

$$X_{dd}(\mathbf{r}_{12}) = X_{dds}(\mathbf{r}_{12}) + u_l(\mathbf{r}_{12}).$$

(14)

The splitting is done subject to the conditions:
\begin{align}
    u(r_{12}) + N_{dd}(r_{12}) &= u_{a}(r_{12}) + N_{dds}(r_{12}), \quad (15) \\
    N_{dd}(r_{12}) + X_{dd}(r_{12}) &= N_{dds}(r_{12}) + X_{dds}(r_{12}). \quad (16)
\end{align}

The short-range function \( u_{a}(r_{12}) \) (going to -\( \infty \) for small distances and healing to 0 for large distances) and its long-range counterpart are then chosen as:

\begin{align}
    u_{a}(r_{12}) &= -2 K_{0}(Q|r_{12} - \bar{a}|) - 2 K_{0}(Q|r_{12} + \bar{a}|), \quad (17) \\
    u_{l}(r_{12}) &= 2 \ln(|r_{12} - \bar{a}|) + K_{0}(Q|r_{12} - \bar{a}|) \\
    &\quad + 2 \ln(|r_{12} + \bar{a}|) + K_{0}(Q|r_{12} + \bar{a}|), \quad (18)
\end{align}

where \( K_{0}(x) \) is the modified Bessel function, and \( Q \) is a cut-off parameter of order 1. We recall that the 2D FT \( \tilde{u}_{l}(q) \) of \( u_{l}(r_{12}) \) is:

\[
\tilde{u}_{l}(q) = -\frac{4\pi}{q^{2}(q^{2} + Q^{2})} \left( e^{iq\bar{a}} + e^{-iq\bar{a}} \right). \quad (19)
\]

The final set of equations is solved by a standard iterative procedure. There is one necessary approximation within the FHNC method in order to obtain a closed set of equations for the nodal and non-nodal functions: a small set of cluster diagrams (corresponding to the so-called elementary diagrams), which cannot be included \textit{ab initio} in the method, needs to be somehow estimated outside the FHNC method. Several schemes have been devised to include the contribution of such diagrams at various levels of approximation, however the simplest approximation of totally neglecting these terms (called the FHNC/0 approximation where we assume \( E_{dd} = E_{de} = E_{ee} = 0 \)) generally leads to very reliable results \( [23, 26, 27, 28] \) and we have adopted it in this paper.

\section*{IV. RESULTS AND DISCUSSIONS}

In this work we applied the FHNC theory to study the BRS state at filling 1/2 of an arbitrary LL. For the sake of simplicity we neglected the elementary diagrams (FHNC/0). This has allowed us to determine to a reasonable accuracy the pair distribution function and the static structure factor. In order to compare the \( \alpha = 0 \) (RR state, \textit{isotropic}) with the \( \alpha \neq 0 \) (BRS state, or \textit{anisotropic}) we studied the properties of the BRS wave function for several \( \alpha \)'s with magnitudes between 0 and 3 (in general \( \alpha = |\alpha|e^{i\theta_{0}} \), but without losing generality we considered only \( \theta_{0} = 0 \)).

In Fig. 1 we plot the pair distribution function \( g(r) \) for \( \alpha = 2 \) [panels (a) and (b)], and the angle-averaged pair distribution function \( \overline{g}(r) \) corresponding to \( \alpha = 0, 1, 2, 2.5 \) and 3 [panels (c) and (d)]. It is interesting to note, for \( \alpha \neq 0 \), the noticeable angle-dependence of \( g(r) \), and the splitting of the triple node at the origin to a simple node at the origin and additional simple nodes at \( r = \alpha \) and angle \( \theta = \theta_{0}, \theta_{0} + \pi \) (\( \theta_{0} = 0 \) in this case). From the energetics point of view [see Eq. (3)], a major consideration is the strong dependence of \( \overline{g}(r) \) on the value of the parameter \( \alpha \). As \( \alpha \) is increased the major peak of \( \overline{g}(r) \) becomes less pronounced and for \( \alpha \approx 3 \) it develops a shoulder for small \( r \) [panel (c)]. In addition, note change in the small-\( r \) behavior of \( \overline{g}(r) \) which switches from \( \propto r^{6} \) (for \( \alpha = 0 \)) to \( \propto r^{2} \) as \( \alpha \) is increased [panel (d)]. In general, for small-\( r \), \( \overline{g}(r) \) has almost no angular dependence \( [40] \), and for \( \alpha \neq 0 \), \( g(r \approx 0, \theta) \approx C_{\alpha} r^{2} \) for \( 0 \leq r \leq 0.5 \), where \( C_{\alpha} \approx 0.024 \alpha^{-1.5} \).

In Fig. 2 we plot the static structure factor \( S(q) \) for \( \alpha = 2 \) (top panel), where the most important feature is the emergence of peaks in \( S(q) \) characteristic of a nematic structure: and the angle-averaged static structure factor \( \overline{S}(q) \) corresponding to \( \alpha = 0, 1, 2, 2.5 \) and 3 (bottom panel). Note the considerable dependence of \( \overline{S}(q) \) on \( \alpha \): as it increases the peak is broadened and flattened, with no significant change in the small-\( q \) behavior.

One can compute the correlation energy per particle either directly from Eqs. (3), (5), or (8) to determine the energy per electron for arbitrary values of the Fermi BRS parameter \( \alpha \), the 2D system width \( \lambda \), and Landau level index \( L \). The following simplified formula can be used in view of Eq. (3):

\[
E_{\alpha}^{L}(\lambda) = \frac{1}{4\pi} \int_{0}^{\infty} dq q \tilde{V}(q, \lambda) \left[ L_{0}(\frac{q^{2}}{2})^{2} \overline{S}(q) - 1 \right], \quad (20)
\]

where \( \tilde{V}(q, \lambda) = (2\pi e^{2}/\epsilon q) \exp(-\lambda q) \) is the 2D FT of the ZDS interaction potential \( [34] \). In addition to allowing straightforward calculations to be extended to any LL, Eq. (20) permits higher numerical accuracy on the calculation of \( E_{\alpha} \) since \( \overline{S}(q) \) saturates exponentially to 1 for relatively small values of \( q \) as compared to \( \overline{g}(r) \).

Fig. 3 shows the energy difference between BRS states with \( \alpha = 1, 2, 2.5 \) and 3, and the isotropic state with \( \alpha = 0 \). Our findings indicate that in the LLL \( (L = 0) \) the Rezayi-Read (RR) state is stable for any \( \lambda \), since all \( \alpha \neq 0 \) states have higher energies (top panel).

The situation changes considerably in higher LLs \( (L \geq 1) \). In general, Fermi BRS states are found to have lower energies and the compressible RR state is unstable towards a nematic state (see lower panels of Fig. 3). Contrary to our findings for 1/3-filled LLs \( [23] \), we do not see a runaway instability but rather find that there are optimal values: \( \alpha_{1}^{*} \approx 2 \) for the first LL \( (L = 1) \), and \( \alpha_{2}^{*} \approx 1 \) for \( L = 2 \). Whereas no BRS state has been so far observed for \( L = 1 \) (likely because another correlated state not considered here is lower in energy) it is likely that the BRS state found here is related to the low-temperature anisotropic conductance found in higher LLs \( [19, 22] \).

At this point it is important to comment on how precise our determination of these energy differences is. There are two aspects to this problem. First, the reader should note that we used an \textit{unprojected} wave function in place of the RR generalization [Eq. (3)]. While it would be highly desirable to incorporate this LL projection operators into the formalism this is not feasible within the FHNC method used here. We should note, however, that the presence of the Jastrow factors in Eq. (3) already provides a considerable projection into the LLL, and is
believed to be particularly effective as far as ground-state properties are concerned [38]. The second aspect is that the FHNC/0 method is essentially a variational method, giving energies that constitute an upper bound to the exact ground state energy [11]. While a precise estimate of these errors can only be made a posteriori by comparing these results with alternative calculations, these methods have proven to be quite reliable in scenarios ranging from other partially filled LLs [24, 37] to 3He systems [38, 39]. While the energy differences we are interested (see Fig. 3) are quite small, and perhaps smaller than the errors in the absolute values of the correlation energy in the states, we remark that these are not uncorrelated errors but systematic deviations due to the nature of the approximations used, and energy differences will likely be considerably more precise.

In conclusion, we applied the FHNC theory to study possible Fermi BRS states in a 1/2-filled LL. We find that the isotropic RR state is stable in the LLL for realistic interaction potentials. In higher LLs, BRS states with nematic order are energetically more favorable than the RR state, perhaps with a direct connection to the anisotropic states observed recently in high LLs [18, 21].

We would like to acknowledge helpful discussions with A.T. Dorsey, M. Fogler, L. Radzihovsky and G. Vignale. This work was supported by the University of Missouri Research Board.

APPENDIX A:

For a Fermi system at density \( \rho \) and spin degeneracy \( g_s \) (1 or 2) the sum of non-nodal (composite) diagrams is given by:

\[
X_{dd}(r_{12}) = e^{u(r_{12})} + N_{dd}(r_{12}) + E_{dd}(r_{12}) - N_{dd}(r_{12}) - 1
\]  

(A1)

\[
X_{de}(r_{12}) = e^{u(r_{12})} + N_{dd}(r_{12}) + E_{dd}(r_{12})
\times \left[ N_{de}(r_{12}) + E_{de}(r_{12}) \right] - N_{de}(r_{12}) ,
\]  

(A2)

\[
X_{ee}(r_{12}) = e^{u(r_{12})} + N_{dd}(r_{12}) + E_{dd}(r_{12}) - N_{ee}(r_{12})
\times \left[ N_{de}(r_{12}) + E_{de}(r_{12}) \right] - N_{ee}(r_{12})
\]  

(A3)

\[
X_{cc}(r_{12}) = e^{u(r_{12})} + N_{dd}(r_{12}) + E_{dd}(r_{12}) - N_{cc}(r_{12})
\times \left[ N_{de}(r_{12}) + E_{de}(r_{12}) \right] - N_{cc}(r_{12})
\]  

(A4)

The chain formation of the nodal diagrams is generated by convolution equations

\[
N_{dd}(r_{12}) = \rho \int dr_3 [X_{dd}(r_{13}) + N_{dd}(r_{13})] P(r_{32}) ,
\]  

(A5)

\[
N_{de}(r_{12}) = \rho \int dr_3 [X_{dd}(r_{13}) X_{de}(r_{12})
\times \left[ N_{de}(r_{13}) + N_{de}(r_{13}) \right] P(r_{12})] ,
\]  

(A6)

\[
N_{cc}(r_{12}) = \rho \int dr_3 [X_{dd}(r_{13}) X_{cc}(r_{32})
\times \left[ N_{cc}(r_{13}) + N_{cc}(r_{13}) \right] P(r_{32})] ,
\]  

(A7)

\[
X_{dd}(r_{13})X_{cc}(r_{32}) + [X_{de}(r_{13}) + N_{ee}(r_{13})] P(r_{32})] ,
\]

(A8)

\[
N_{cc}(r_{12}) = \rho \int dr_3 \left[ l(r_{13})/g_s + X_{cc}(r_{13})
\times \left[ N_{cc}(r_{13}) + N_{cc}(r_{13}) \right] X_{cc}(r_{32}) ,
\]

where

\[
P(r_{ij}) = X_{dd}(r_{ij}) + X_{de}(r_{ij}) + \rho \int dr_k [X_{dd}(r_{ik}) X_{cc}(r_{kj}) - X_{de}(r_{ik}) X_{de}(r_{kj})].
\]

The pair distribution function is then given from:

\[
g(r_{12}) = 1 + X_{dd}(r_{12}) + N_{dd}(r_{12})
+ 2 \left[ X_{de}(r_{12}) + N_{de}(r_{12}) \right] + X_{cc}(r_{12}) + N_{cc}(r_{12}) .

40 The absence of angular dependence on \( g(r, \theta) \) for small \( r \) can be easily understood by noting that in the small-\( r \) limit: \( g(r \approx 0, \theta) \propto \exp[u_s(r \approx 0, \theta)] 1 - l(r \approx 0)^2/g_s \), \( (g_s = 1) \) where \( u_s(r, \theta) \) is given from Eq. \( \text{(17)} \). The second term in the above expression is angle-independent and represents the zero of the Pauli principle. For short distances: \( \lim_{r \to 0} K_0(Qr) = -\ln(Qr/2) - \gamma \) (\( \gamma = 0.5772 \ldots \) is Euler’s constant), therefore \( u_s(r \approx 0, \theta) \) and by consequence \( g(r \approx 0, \theta) \) is angle-independent in this region. For more details see Ref. \( \text{[24]} \).

FIG. 1. Pair distribution function for the BRS state at $\nu = 1/2$. (a) $\alpha = 2$, surface plot of $g(r)$ (the surface for $y < 0$ was removed for clarity); (b) $\alpha = 2$, dotted lines: $g(r, \theta)$ for various $\theta \in [0, 2\pi]$, full line: angle averaged $\overline{g}(r)$; (c) Angle averaged $\overline{g}(r)$ for $\alpha = 0, 1, 2, 2.5$ and $3$; (d) Small-$r$ behavior of $\overline{g}(r)$, lines are fitting curves. Note the discrete nodes of $g(r, \theta)$ at $r = \alpha$, $\theta = \theta_\alpha, \theta_\alpha + \pi$ ($\theta_\alpha = 0$ in this case). Calculations were performed in the FHNC/0 approximation.
FIG. 2. Static structure factor for the BRS state at $v = 1/2$. (a) $\alpha = 2$, surface plot of $S(q)$ (the surface for $q_y < 0$ was removed for clarity); (b) Angle averaged $S(q)$ for $\alpha = 0, 1, 2, 2.5$ and 3. Note the presence of peaks in $S(q)$ consistent with a nematic structure. Calculations were performed in the FHNC/0 approximation.

FIG. 3. Energy per particle of the Fermi BRS states with $\alpha = 1, 2, 2.5$ and 3 relative to the isotropic ($\alpha = 0$) state: $\Delta E_{\alpha}(\lambda) = E_{\alpha}(\lambda) - E_{0}(\lambda)$ for the LLL ($L = 0$) and higher LL-s as function of the short distance cut-off parameter $\lambda$. Energies are in units of $e^2/(\epsilon\ell_o)$. Note that in the LLL, the Fermi BRS states always have an energy higher than the isotropic state, whereas in higher LLs ($L = 1, 2$) there are ranges of $\lambda$ for which Fermi BRS states are favorable.
