Abstract

Background Advances in oncology led to a substantial increase in the number of patients requiring admission to the ICU. It is significant to confirm which cancer critical patients can benefit from the ICU care service like noncancer patients.

Methods An observational retrospective cohort study using intensive care unit (ICU) admissions of Medical Information Mart for Intensive Care III from the Beth Israel Deaconess Medical Center in Boston, MA, USA between 2001 and 2012 was conducted. Propensity score matching was used to reduce the imbalance between two matched cohorts. ICU patients with cancer were compared with those without cancer in terms of patients’ characteristics and survival.

Results There were 38,508 adult patients admitted to ICUs during the period. The median age was 65 years (IQR, 52-77) and 8,308 (21.8%) had an underlying malignancy diagnosis. The noncancer group had a significant survival advantage at the point of 28-day, 90-day, 365-day and 1095-day after ICU admission compared with cancer group ($P < 0.001$ for all) after PSM. Subgroup analysis showed that the diagnosis of malignancy didn't decrease 28-day and 90-day survival when patients’ age $\geq 65$-year, patients in surgical intensive care unit or cardiac surgery recovery unit or traumatic surgical intensive care unit, elective admission, patients with renal replacement therapy or vasopressor support ($P > 0.05$ for all).

Conclusions Malignancy is a common diagnosis among ICU patients. Patients without cancer have a survival advantage compared with patients with cancer in the short- and medium-term. However, in selected groups, cancer critical patients can benefit from the ICU care service like noncancer patients in the short-term.

Background

Historically, the presence of malignant disease had been a common reason for refusal of admission to intensive care unit (ICU) because of poor prognosis and high costs [1–3]. Survival of cancer patients has increased over the last three decades due to a greater awareness of early signs and better treatment[4, 5]. Patients with cancer require ICU admission for postoperative care after major surgical resections, severe cancer- or chemo-radiation- or immunotherapy related complications, and concurrent severe acute illnesses[6, 7]. About 1 in 20 patients experienced a critical illness resulting in ICU admission within 2 years of cancer diagnosis and around one in seven patients admitted to general ICUs had a malignancy[6, 8, 9].

The outcome of cancer patients admitted to ICU is strongly dependent on the type of admission. Puxty et al.[10] studied 25,017 surgical admissions to general ICUs in the West of Scotland, and found that ICU and hospital mortality were lower in the group of ICU patients with cancer compared with noncancer patients. Bos et al.[11] reported on the characteristics and outcome of more than 15,000 cancer patients with an unplanned emergency admission to general ICUs in the National Intensive Care Evaluation registry between January 2007 and January 2011. They demonstrated that cancer patients have increased hospital mortality when compared with noncancer patients when admitted for medical reasons. When physicians decide to admit cancer patients to ICU, it should be kept in mind that the admitted cancer patients should be likely to benefit from ICU service. The challenge facing ICU physicians is to identify which cancer patients are likely to benefit from ICU care like noncancer patients. Most previously published studies didn't include a comparison group of patients without cancer; thus, it is difficult to determine the effect of cancer within the same ICU or hospital setting[11–13].

Our primary objective was to explore which critical ill patients with cancer can benefit from the ICU care like critical ill patients without cancer so that we can treat the diagnosis of malignancy as a chronic disease (such as hypertension, diabetes). We performed this study via available database of Medical Information Mart for Intensive Care III (MIMIC III) based on propensity score matching (PSM).

Methods

Clinical database

The MIMIC-III database is a large and freely available database comprising more than 40,000 patients in the ICU of the Beth Israel Deaconess Medical Center in Boston, MA, USA between 2001 and 2012. Our access to the database was approved after completion of the Collaborative Institutional Training Initiative (CITI program) web-based training course called “Data or Specimens Only research” (Record ID: 36067767).

Data extraction
Structured Query Language (SQL) with PostgreSQL (version 9.6) was used to extract data from MIMIC-III. Demographics (gender, age, ethnicity), ICU type, admission group (elective and emergency), reasons for ICU admission were extracted for adult patients (≥ 18 years) admitted to ICU. The severity of illness score was evaluated by the Sequential Organ Failure Assessment (SOFA) score[14], Simplified Acute Physiology Score II (SAPSII)[15], Logistic Organ Dysfunction Score (LODS)[16], Oxford Acute Severity of Illness Score (OASIS)[17] and Acute Physiology Score III (APS III)[18]. For parameters of these five scoring systems, only data within 24 h after ICU admission were extracted and missing components for calculation were treated as normal (usually zero). Comorbidities were evaluated using the Elixhauser comorbidity system which scores a wide range of comorbid diseases and conditions according to the severity of organ decompensation and prognostic impact[19], the higher the score, the worse the patient’s health. Other extracted data included mechanical ventilation (MV), vasopressor usage, renal replacement therapy (RRT), sepsis, hospital infection. Survival information was obtained from Social Security Death Index records. The endpoints of our study were 28-day, 90-day, 365-day and 1095-day survival after ICU admission.

**Population Selection Criteria**

Patients were not allowed to reenter the study after their first ICU admission. Enrolled cancer subjects were patients with diagnosis of malignancy according to International Classification of Diseases, Ninth Revision code (ICD-9). Suspected infection [20] was identified using the International Classification of Diseases, Ninth Revision, Clinical Modification codes (ICD-9-CM). The diagnosis of sepsis was based on the third international consensus definitions for sepsis and Septic Shock (Sepsis-3)[21]. The screening process of enrolled patients is shown in Fig. 1.

**Statistical analysis**

Categorical variables were described as the number and percentage, and their differences among groups were compared using Chi-squared test. Noncontinuous variables and continuous variables that didn’t follow normal distribution were expressed as median and interquartile range (IQR), and were analyzed with non-parametric methods (Mann-Whitney-Wilcoxon for two groups, Kruskal-Wallis for multi-groups). Continuous variables that followed normal distribution were expressed as mean and standard deviations, and t-test (two groups) or Analysis of Variance (ANOVA) (multiple groups) was used for these variables. Kaplan-Meier curves were used to calculate the survive rate and the log-rank test was used for comparisons between groups. The use of propensity score analysis aimed to reduce the imbalance between two matched cohorts. Standardized difference (SDD) before and after matching were plotted to show the effect of matching. In the cohort of propensity score-matched subjects, the SDD of all covariates between cancer group and noncancer group were < 10%, which suggested that the propensity score matching appropriately adjusted for the initial selection bias. The bias in subgroups after successful PSM could also be considered as balanced[22]. A P value < 0.05 was considered statistically significant. Statistical analyses were performed using Stata, version 14.0 (Stata Corp).

**Results**

Characteristics of the patients with cancer and without cancer

During the study period, there were 38,508 patients whose age were older than 18 years admitted to ICUs in the Beth Israel Deaconess Medical Center in Boston, MA, USA between 2001 and 2012, of whom 16,715 (54.7%) were male. The median age was 65 years (IQR, 52–77), and 8,308 (21.8%) had an underlying malignancy diagnosis. Table 1 gives patient characteristics for admissions to ICU with and without a diagnosis of malignancy before and after PSM. ICU patients with cancer tended to be older than patients without cancer with median (IQR) age 70 (60–79) VS 63 (50–77) years (P < 0.001). The population without cancer admitted to ICU as an emergency was 85.9% (25,993 of 30,200 patients) in contrast to 78.1% (6,485 of 8,308 patients) of the population with cancer. Compared with patients with noncancer, patients with cancer were more likely to be admitted by surgical intensive care unit (SICU) (21.5% VS 15.2%) and medical intensive care unit (MICU) (42.0% VS 33.6%). The percentage of the noncancer patients in coronary care unit (CCU), cardiac surgery recovery unit (CSRU) and traumatic surgical intensive care unit (TSICU) were more than that of cancer patients. The admission reasons were otherwise similar between the cancer and noncancer groups with cardiovascular dysfunction, liver disorder, mental disorder, renal disorder, respiratory dysfunction, and coagulation dysfunction. Cancer patients tend to have high critical illness score compared with noncancer patients, SAPSII [39(26–46) VS 31(23–41), P < 0.001], APSIII [40(30–53) VS 37(27–51), P < 0.001]. The Elixhauser comorbidity index score of cancer patients was also significantly higher than noncancer patients [9(2–17) VS 3(0–9), P < 0.001]. Respiratory support was the most common mode of support for both the cancer and noncancer groups at 40.3% (3,351 of 8,308 patients) and 47.2% (14,262 of 30,200 patients), respectively. Cardiovascular support was provided to 27.0% of the cancer group (2,240 of 8,308 patients) and 30.2% of the noncancer group (9,114 of 30,200 patients). Renal replacement therapy was not commonly provided in either group, but those patients in the cancer group had a lower prevalence of RRT [147 of 8,308 patients (1.8%)] when compared with the noncancer group [889 of 30,200 patients (2.9%), P < 0.001]. Patients with cancers were more likely to have a higher...
frequency of infection (42.7% VS 38.6%, $P<0.001$) and sepsis (7.8% VS 6.5%, $P<0.001$). After the propensity scores matched using 1:1, the covariates of the cancer group and noncancer group were balanced with a standard difference less than 5% (Fig. 2).
# Table 1
Comparison of variables between Intensive care patients with cancer and without cancer before and after propensity score matched analysis

| Variable                  | ALL Patients before PSM | Patients after PSM |
|---------------------------|-------------------------|--------------------|
|                           | N = 38,508              |                    |
|                           | Noncancer(N = 30,200)   | Cancer (N = 8,308) |
|                           |                         |                    |
| Age, median (IQR), Y      | 65(52–77)               | 63(50–77)          |
|                           | < 0.001                 | 70(60–79)          |
| P Value                   | 44.2                    | 72(59–81)          |
| SDD                       | 0.8                     | 69(59–79)          |
|                           | 0.921                   | 1.000              |

Abbreviations: LOS, length of stay; Intensive care unit, ICU; propensity score matching, PSM; IQR, 25–75% interquartile range.

In the crude model, 28-day, 90-day, 365-day and 1095-day survive rate of noncancer group were 88.0%, 84.3%, 79.1% and 72.6%, respectively, which were higher than the cancer group with 81.3%, 72.9%, 59.3% and 48.3%, respectively. After PSM, the noncancer group still had a significant survive advantage at the point of 28-day, 90-day, 365-day and 1095-day after admission compared with cancer group ($P < 0.001$ for all) in the overall population (Fig. 3). Cancer patients had a similar length of ICU stay and slightly longer hospital stay (7.3-day VS 6.8-day, $P < 0.001$) compared with noncancer patients.

Subgroups analysis of short and medium-term survival of critically ill patients between with cancer and without cancer after PSM (Table 3)
Table 3
28-day and 90-day Survive in Patients With and Without Cancer by Admission Features after propensity score matching

Abbreviations: Sequential Organ Failure Assessment, SOFA; Simplified Acute Physiology Score II, SAPSII; Logistic Organ Dysfunction Score, LODS; Oxford Acute Severity of Illness Score, OASIS; Acute Physiology Score, APSIII; Surgical intensive care unit, SICU; Medical intensive care unit, MICU; Coronary care unit, CCU; Cardiac surgery recovery unit, CSRU; Traumatic surgical intensive care unit, TSICU; mechanical ventilation, MV; renal replacement therapy, RRT.
The noncancer patients had survive advantage than cancer patients in MICU \((P<0.001, \text{Supp. Figure 1})\). However, when patients admitted by SICU, the survive advantage disappeared at the point of 28-day and 90-day \((P>0.05\text{ for both, Supp. Figure 2})\). Table 3 shows 28-day and 90-day survive in patients with and without cancer stratified according to distinct patient subgroups. Compared with noncancer group, 28-day and 90-day survive rate was lower in the cancer group when patients’ age < 65, black, in MICU, emergency admission (Supp. Figure 3), admission because of cardiovascular or respiratory or coagulation dysfunction, Elixhauser comorbidity index score $\geq 4$, and patients without RRT or vasopressor support \((P<0.05\text{ for all})\). 28-day and 90-day survive rate showed no difference between cancer and noncancer group when patients’ age $\geq 65$, patients in SICU or CSRU or TSICU, elective admission (Supp. Figure 4), patients with RRT or vasopressor support \((P>0.05\text{ for all})\). Although when patients were Asian or White or Hispanic, admission because of liver or mental or renal disorder, Elixhauser comorbidity index score $< 4$, patients with cancer showed no different 28-day survive compared with noncancer patients \((P>0.05\text{ for all})\), the survive advantage appeared at 90-day survive for noncancer patients \((P<0.05\text{ for all})\). However, for patients in CCU, cancer group has higher 28-day survive rate than the noncancer group \((P=0.022)\) and the survive advantage disappeared at the point of 90-day \((P=0.409)\).

**Discussion**

The interesting aspect of our study was the inclusion of consecutive admissions of cancer and non-cancer patients during the same time period. In the crude model, the higher survive rate was found in ICU patients with noncancer than those with cancer in the overall population at the point of 28-day, 90-day, 365-day and 1,095-day. Using a one-to-one propensity score matched analysis to address selection bias, we found that this difference was narrowed though noncancer patients still had a slight survival advantage. In this study, we accepted five criticality scores to evaluate the illness of patients. The criticality scores of cancer patients were higher than those of noncancer patients. No matter in the group with high critical illness score or the group with low critical illness score, the 28-day and 90-day survive of cancer patients was significantly worse than that of noncancer patients \((P<0.05\text{ for both})\). ICU patients with cancer tended to be older than patients without cancer and cancer patients usually had a worse outcome when patients’ age $> 65$. However, the poor outcome wasn’t associated with the diagnosis of malignancy.

To further subgroup analysis of 28-day and 90-day survive associated with cancer diagnosis, we found that the diagnosis of the malignancy didn’t decrease the 28-day and 90-day survival rates in selected groups. When patients admitted by MICU, 28-day and 90-day survive was higher in noncancer patients than cancer patients. However, cancer patients who were admitted by SICU had similar outcomes compared with those of noncancer patients. This finding is in keeping with those of previous studies\[10, 11\]. For cancer patients admitted to MICU, the stage was usually late\[13\] and the cancer related therapy may lead to immunosuppressive status\[23\], so the early prognosis was usually poor. However, for patients in SICU, the stage was usually early\[13\] and the tumor resection have reduced most of the tumor load, so the diagnosis of malignancy had few effects on their short-term prognosis. So we can concluded that short-term survive rates especially differed between cancer and non-cancer patients admitted to ICU because of medical reasons, whereas differences between cancer and non-cancer patients were either not existing or modest in SICU.

Emergency or elective admissions often affect the prognosis of patients in the ICU. In the present study, when patients admitted as elective admission, it showed no difference of survive at the point of 28-day and 90-day between cancer and noncancer patients although the difference appeared at the point of 365-day. When patients admitted as emergency, the noncancer patients has a survive advantage within 1095 days after ICU admission. Bos et al.\[11\] also reported the similar outcome. They demonstrated that emergency ICU admission is associated with a survive advantage in patients with noncancer. It is associated with a higher incidence of acute comorbidity and a greater severity of illness on admission in the cancer group\[11\].

In the present study, patients with cancer had a greater need for intensive support (eg, MV, vasopressor administration, and RRT), which was consistent with previous literature\[24\]. In patients with MV support, we found that noncancer patients had survive advantage at the point of 28-day and 90-day after ICU admission. Hsiue et al.\[25\] compared 518 patients with solid cancers with 1362 non-cancer patients receiving MV admitted to ICU between 2012 and 2014. They found that the 28-day and 90-day mortality rates were higher in cancer patients than in noncancer patients \((45.2\% \text{ vs. } 29.4\%, \text{ and } 65.6\% \text{ vs. } 37.7\%, \text{ respectively, both } P<0.001)\). It remains controversial to start RRT for acute renal failure in critically ill patients with cancer because of the poor outcome and high costs\[26–31\]. However, this controversy lacked large sample research in previous literature. In our study, for patients in need of RRT, the diagnosis of malignancy didn’t decrease their 28-day and 90-day survive in this study. Benoit et al. \[3\] and Macciariello et al.\[32\] also demonstrated that though the early prognosis of cancer patients with acute renal failure in need of RRT is poor, the malignancy itself is not an independent risk factor that affects the prognosis. Cancer patients with shock admitted to ICU usually have a poor prognosis\[33\]. Previous study reported the in-hospital mortality rate of cancer patients with sepsis shock seemed to be higher than that of noncancer...
patients[34–36]. However, they did not include a control group of septic shock patients without cancer. In the present study, when cancer patients with RRT or vasopressor support admitted to ICU, they a had worse short-term outcome, but the poor outcome was not caused by the diagnosis of malignancy.

It has found chronic disease burden to be significantly associated with short-term outcome[37, 38]. We accepted a single numeric score based on the Elixhauser comorbidity index to describe the chronic health status of patients[19]. Cancer patients seems to be with more chronic comorbidities than noncancer patients. In this study, for those patients with poor chronic health or limited functional status, the diagnosis of malignancy had been demonstrated to be associated with poorer 28-day survival. While for patients with a better health status (Elixhauser comorbidity score < 4), the survive difference disappeared at the point of 28-day though the noncancer group still had survive advantage at the point of 90-day. So the diagnosis of malignancy have a more effect on patients with much comorbidities.

Patients with cancer diagnosis were more likely to have infections or sepsis compared with those noncancer patients in this study. Cancer has been reported in about 17% associated with sepsis in MICU[39]. Sepsis is one of the major causes of ICU admission for cancer patients[7] and is an important cause of hospital mortality and morbidity[9]. Treatment of cancer has contributed to a growing number of immunocompromised patients with an increased incidence of hospital infections; immunosuppression can result in a greater use of antibiotics and more infections associated with multi-resistant microorganisms[23]. In our study, cancer patients with hospital infection or sepsis had worse prognosis than noncancer patients with hospital infection or sepsis. Therefore, for patients with malignancy, we should pay attention to the status of potential infections.

The strength of the present study includes the low confounding bias due to equivalence of covariates between the two study groups in the propensity score-matched cohort. The propensity score method creates a model that reflects the effects of risk factors on the exposure. Matching using a single summary variable that predicts the probability of being exposed as a function of the confounders creates a statistical model with fewer assumptions and may lead to improved estimates of exposure effects in some settings[22]. This study also included a comparison group of patients without cancer to determine effect of cancer within the same ICU setting. Our study also had shortcomings, firstly, the cancer stage is not available, which may be a factor that affects the early prognosis of the patients. Secondly, the time of diagnosis of malignancy was not consistent, which may be more than 2 years earlier before their ICU admission. Those patients with more than 5-years tumor free survive can be considered as cured completely.

Conclusions

Advances in oncology led to a substantial increase in the number of patients requiring admission to the ICU. In the overall population, noncancer patients had a survive advantage of short- and medium-term. When patients’ age ≥ 65 years, patients in SICU or CSRU or TSICU, elective admission, patients with RRT or vasopressor support, the diagnosis of malignancy didn't decrease their short-term survive and cancer patients can benefit from ICU intensive care like noncancer patients. These findings can help us make cancer-related prognosis judgments and make corresponding clinical decisions.
