Comment on "The shape and composition of interstellar silicate grains"
J. P. Bradley and H. A. Ishii

Institute of Geophysics and Planetary Physics, Lawrence Livermore National Laboratory, Livermore, CA 94550, USA
Accepted for publication April 4, 2008

In the paper entitled "The shape and composition of interstellar silicate grains" (A& A, 462, 667-676 (2007)), Min et al. explore non-spherical grain shape and composition in modeling the interstellar 10 and 20 µm extinction features. This progression towards more physically realistic models is vitally important to enabling valid comparisons between dust observations and laboratory measurements. Min et al. proceed to compare their model results with GEMS (glass with embedded metals and sulfides) from interplanetary dust particles (IDPs) and to discuss the nature and origin of GEMS. Specifically, they hypothesize that GEMS are remnants interstellar (IS) amorphous silicates. From a comparison of the mineralogy, chemical compositions, and infrared (IR) spectral properties of GEMS with their modeling results, Min et al. conclude that "the composition of interstellar medium (ISM) silicates is not consistent with that of GEMS" and that "GEMS are, in general, not unprocessed leftovers from the diffuse ISM". These original conclusions were based, however, on erroneous GEMS data.

In the accompanying Erratum, Min et al. provide corrections, evaluate the impact on the paper and retain their original conclusions that GEMS chemical properties are inconsistent with the bulk ISM and that most GEMS formed in the early solar system. We respectfully disagree. With the corrections, two additional fundamental chemical properties of GEMS (Mg/(Mg+Fe) and O/Si), as well as a key optical property, the 10 µm infrared silicate feature, are consistent with those of the IS amorphous silicates as predicted by the Min et al. model, which itself relies on assumptions. The additional properties further solidify the remarkable similarity between the exotic properties of GEMS and IS amorphous silicates (Bradley 1994; Flynn 1994; Goodman & Whittet 1995; Martin 1995; Bradley et al. 1999). We agree that the match is imperfect, but given the statistical limitations of comparing less than a microgram of GEMS with their modeling results, Min et al. conclude that "the composition of interstellar medium (ISM) silicates is not consistent with that of GEMS" and that "GEMS are, in general, not unprocessed leftovers from the diffuse ISM". These original conclusions were based, however, on erroneous GEMS data.

1. Interstellar GEMS versus solar system GEMS

There is general agreement that circumstellar (CS) outflows from AGB stars are major sources of IS silicates and that at least some IS silicates are likely to retain a memory of their presolar CS origins (e.g. Ebel 2000). Whether GEMS are processed or not, the presolar IS origin (that is, extrasolar as opposed to solar system formation) of some of them has been rigorously confirmed through measurements of non-solar oxygen (O) isotope abundances (Messenger et al. 2003; Floss et al. 2006). In the accompanying Erratum, Min et al. acknowledge that these isotopically anomalous GEMS were indeed part of the population of IS amorphous silicates. However, they advocate an early solar system origin for most GEMS. Their arguments rest largely on compositional evidence. One concerns isotopic compositions and the other concerns chemical (elemental) compositions of GEMS.

1.1. Isotopic composition considerations

The isotopic argument exploits a dilemma that has long confronted meteoricists. Most GEMS have normal (solar) oxygen isotopic compositions suggesting that they could have formed in the solar system. However, they could equally have formed outside of the solar system. It is well known that only a small fraction of ISM dust can have a non-solar isotopic composition, yet a non-solar isotopic composition is currently the only way to rigorously identify presolar ISM dust. This dilemma is eloquently articulated by the late Robert M. Walker:

"It is (also) true that pre-existing interstellar grains might not, on the average, be very different from solar system material. Although there is strong evidence that some circumstellar grains with distinctive isotopic signatures have survived intact in meteorites, theoretical calculations indicate that most grains are quickly destroyed in the diffuse interstellar medium (Seab & Shull 1986). Thus, the grains found in a protostellar gas-dust cloud may themselves consist of interstellar dust grains whose compositions have been homogenized in the interstellar medium to give compositions similar to those of solar system values. In this connection, it is interesting to note that the isotopic compositions of galactic cosmic rays is, with some exceptions, not strikingly different from average solar system material (Wiedenbeck 1984)." (from Bradley et al. 1988).

The ISM is a giant materials recycler (Seab & Shull 1986; Jones et al. 1994; Ebel 2000; Westphal & Bradley 2004), and it is likely no accident that presolar grains found in meteorites are a "who’s who" of the most robust and persistent minerals (e.g. silicon carbide (SiC), corundum (Al₂O₃), diamond, graphite, etc.). Silicate minerals, on the other hand, are more susceptible to modification and destruction by aqueous alteration, heating, shocks, and irradiation (Bradley 1994; Keller & McKay 1997).
It has been argued that even some GEMS without detectable isotope anomalies are probably presolar grains from the ISM. Min et al. (2000) assert that in some cases GEMS are presolar IS silicates because of their petrographic setting, i.e. they are embedded within carbonaceous material with non-solar D/H isotopic composition. The same petrographic argument was used to argue that titanium carbide crystals in a meteorite (too small to measure isotopic composition by instruments at that time) embedded within isotopically anomalous graphite spherules are "ipso facto" presolar grains (Bernatowicz & Cowsik 1997). The advent of the NanoSIMS later proved this claim to be correct (Stadermann et al. 2005). Messenger et al. (2007) even cite neighboring isotopically anomalous (15N-rich) carbonaceous material to argue that some silicates in IDPs with marginal isotope anomalies are likely presolar grains. It follows from these arguments that the petrographic association of presolar organic material with isotopically anomalous as well as isotopically normal GEMS in IDPs strongly suggests that both types of GEMS were present together in the same presolar environment(s).

Although a non-solar isotopic composition proves that some GEMS are IS grains, that is, they resided in the ISM, a solar isotopic composition does not prove that other GEMS did not reside in the ISM, as Min et al. acknowledge in the accompanying Erratum. While some CS silicates retain their isotopic signatures, we may expect a greater abundance of IS silicates that have been processed in the ISM beyond ready isotopic recognition of their parentage: The low relative abundance of GEMS exhibiting detectable isotope anomalies is consistent with the expected properties of ISM-processed grains. Furthermore, whether a given GEMS is identified as isotopically anomalous or not depends to a large extent on the instrument used to make the measurement. Indeed, presolar grain abundances depend on instrumental resolution as well as confidence levels used for defining a grain as anomalous. Prior to the advent of the NanoSIMS, no presolar silicates were discovered. With the NanoSIMS, presolar silicates were soon discovered, and 80% of them are GEMS in CP IDPs (Messenger 2007). However, even with NanoSIMS the sub-nanogram masses of individual GEMS, combined with measurement sensitivity limits, mean that only relatively large isotope anomalies in large individual GEMS can be reliably identified at this time (Messenger et al. 2007).

1.2. Chemical composition considerations

The chemical argument centers on the average major element chemical compositions of GEMS, which Min et al. claim are inconsistent with ISM grain abundances derived by fitting to astronomical measurements. GEMS have too little Mg, Ca and Fe and too much S relative to ISM abundances (Keller & Messenger 2000). These average element abundances imply that GEMS were not members of the ISM grain population. However, even isotopically anomalous GEMS known to have been members of the ISM grain population have chemical compositions that are inconsistent with ISM grain abundances (Table I). The "remarkable similarity" between isotopically anomalous and isotopically solar GEMS reported by Keller & Messenger (2007b) and mentioned in the accompanying Erratum indicates that bulk chemical composition alone cannot be used to categorize individual GEMS according to their original formation location (in the early solar system versus a presolar (non-solar system) source). With additional statistics over the coming years, the average bulk chemical compositions of the sub-population of isotopically anomalous GEMS can be better assessed.

S/Si exceeds the ISM upper limit in GEMS in general and in all of the (isotopically anomalous) IS GEMS that have been measured to date in particular (Table I). (We emphasize that S is not well quantified in the ISM due to oversaturation of the absorption lines (Sofia 2004).) Min et al. propose that GEMS may have acquired their elevated S/Si contents via gas-phase sulfidization in the collapsing solar nebula cloud or in the protoplanetary disk phase. In support of sulfidization, Min et al. report preliminary evidence by x-ray mapping that sulfides appear to be located preferentially at the outer edges of GEMS.

In the accompanying Erratum, Min et al. suggest the location of sulfides in GEMS is currently an open question. We note that a preference toward exterior sulfides is unnecessary to support sulfidization, and the original supporting reference (Keller et al. 2005) does not show that sulfides are located at the outer edges of GEMS. Furthermore, other published data report GEMS with sulfides located within their interiors (e.g. Keller & Messenger 2005; Dai & Bradley 2005; Zolensky et al. 2006) as well as GEMS with sulfides located preferentially within their interiors (e.g. Bradley 1994; Bradley et al. 1999; Bradley & Dai 2004; Westphal & Bradley 2004). While there are likely examples of GEMS with sulfides located at the edges (all other distributions having been reported), all of the published data cited above, obtained using imaging, electron diffraction, nanoprobe (x-ray) analyses, and chemical mapping, indicate that sulfides are not located preferentially at the edges of grains. It is certainly possible that IS GEMS were indeed sulfidized in the solar nebula cloud, but experimental evidence to support this hypothesis has been sought and found absent. In any case, whether GEMS were sulfidized in the solar nebula is tangential to the key issue of whether they are remnant presolar IS silicates. Indeed, molecular cloud formation and dissipation is a common occurrence in the ISM, and ISM grains processed, mantled and accreted in other IS molecular clouds and then re-injected into the ISM will not be readily distinguishable from those processed in our own molecular cloud.

2. A chemical signature of ISM processing of GEMS?

Can the chemical compositions of GEMS tell us anything about their origins and/or mechanisms of formation? Perhaps. Mg/Si ratios have been published for a small number of GEMS with non-solar isotopic compositions to date, and they show an intriguing trend. They tend to be enriched relative to the mean Mg/Si ratio of 242 GEMS (Table I). Bradley (1994) proposed that the chemical properties of GEMS reflect exposure to irradiation during their prolonged lifetimes in the ISM. Although there are undoubtedly additional erosional processes acting to modify element ratios in the ISM (Jones 2008; Tielens 1998; Westphal & Bradley 2004), the hypothesis that irradiation is the dominant effect can be tested: Although forsterite (Mg/Si=2), enstatite (Mg/Si=1) and silicate glasses (Mg/Si unknown) have all been identified in CS outflows and/or the ISM (Molster & Waters 2003, Matzel et al. 2008), CS and IS silicates are believed to be, on average, Mg-rich (e.g. Molster & Waters 2003). Irradiation of Mg-rich silicates can cause chemical gradients and changes in the relative propor-
to yield statistically relevant conclusions. We note that Mg

3. Summary

The central question regarding the origin of GEMS is whether, (A) they are presolar IS amorphous silicates that survived the collapsing molecular cloud and subsequent protoplanetary disk stages of the formation of our solar system to be incorporated into IDPs (Bradley 1994), or (B) they are mostly grains formed in the solar nebula (Keller & Messenger 2004, 2007b). If IS amorphous silicates survived, can we recognize them? The answer is yes, but it is a conditional yes. Isotopically anomalous GEMS have been identified that, during transport through the ISM and formation of the solar system, retained some portion of the isotope signatures of their formation in presolar CS environments. These GEMS were undeniably part of the population of presolar IS silicates. They may be analogues of the amorphous silicate grains observed in the outer disks of other young stars (van Boekel et al. 2004). The simplest explanation for those observed grains is that they are IS amorphous silicates that have escaped significant heating in the (outer) accretion disks (van Boekel 2007), and laboratory heating experiments indicate that GEMS also escaped significant heating in the solar nebula accretion disk (Brownlee et al. 2005).

The isotopic compositions of most GEMS are normal (solar) within the detection limits of current analytical ion microprobes, and for those not petrographically associated with presolar material, their origin may remain an open question for the foreseeable future. However, invoking Occams razor, the similarity in the properties between isotopically anomalous and normal GEMS favors presolar origin and residence in the ISM for all GEMS, especially since both are found in petrographic association with isotopically anomalous presolar organic material in IDPs. While it is possible that some isotopically normal GEMS formed in the solar system, it would indeed be remarkable, and probably unprecedented, that a population of grains as exotic as GEMS, found in only one class of meteoritic material (CP IDPs), having a similar size distribution, mineralogy, petrography and bulk chemical composition, arose by different mechanisms at different times in the environments of different classes of stars (evolved AGB stars versus protostellar nebulae like the solar nebula).
How exciting that we do, indeed, have samples of presolar IS amorphous silicates, one of the fundamental building blocks of solar systems.

Acknowledgements. We acknowledge funding though the NASA Cosmochemistry Program (NNH07A099I) and Origins of the Solar System Program (NNH04AB521). We also thank M. Min and coauthors for a lively exchange that has proven invaluable in clarifying our understanding of the intriguing topics of GEMS and amorphous interstellar silicates. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.
