Supporting Information

ABSTRACT: In this work we report the effect of the hard block dianhydride structure on the overall properties of partially biobased semiaromatic polyimides. For the study, four polyimides were synthesized using aliphatic fatty dimer diamine (DD1) as the soft block and four different commercially available aromatic dianhydrides as the hard block: 4,4'-isonicotinic anhydride (BPA), 4,4'-oxazolidinedione (ODPA), 4,4'-hexafluoroisopropylidenediphenyl (HADPA), and 3,3',4,4'-biphenyltetraanhydride (BPA). The polymers synthesized were fully organosoluble thermoplastic branched polyimides with glass transition temperatures close to room temperature. The detailed analysis took into account several aspects of the dianhydrides structure (planarity, rigidity, bridging group between the phthalimides, and electronic properties) and related them to the results obtained by differential scanning calorimetry, rheology, fluorescence and broadband dielectric spectroscopy. Moreover, the effects of physical parameters (crystallization and electronic interactions) on the relaxation behavior are discussed. Besides the presence of the bulky branched soft block given by the dimer diamine, all polyimides showed intermolecular charge transfer complexes, whose extent depends on the electronic properties of the dianhydride hard block. Furthermore, the results showed that polyimides containing flexible and bulky hard blocks turned out fully amorphous while the more rigid dianhydride (BPA) led to a nanophase separated morphology with low degree of crystallinity resulting in constrained segmental relaxation with high effect on its mechanical response with the annealing time. This work represents the first detailed report on the development and characterization of polyimides based on a biobased fatty dimer diamine. The results highlight the potential of polymer property design by controlled engineering of the aromatic dianhydride blocks.

INTRODUCTION

Due to increased concerns regarding environmental sustainability, highly directed by growing and demanding ecological regulations, renewable resources are increasingly receiving both industrial and academic attention.1–3 Among the different renewable sources vegetable oils are generally considered the most important class due to their availability and versatility. Vegetable oils are used to synthesize different types of polymers such as polycarbonates, polyurethanes, polyesters, polyethers, polyamides, and polyolefins for paints, adhesives, composites, and biomedical applications.4 Various thermoset and thermoplastic polymers can be obtained, resulting in miscellaneous characteristics to meet many different industrial requirements, thereby confirming vegetable-oil based polymers’ potential as alternatives to petroleum-based ones.5,6 Vegetable oils are composed of different triglycerides which are the esterification products of glycerol with various fatty acids. The heterogeneity and variability of the triglycerides, which is due to the statistical distribution of fatty acids per triglyceride, makes a clear and reproducible correlation between the material properties and the monomer structures difficult. However, utilizing difunctional fatty acid-based monomers (diols, diamines, and diacids) with a well-defined molecular structure can lead to biobased polymers with better tunable properties.8 Fatty dimers have been used in the past to prepare polymers with innovative molecular architectures, such as supramolecular polymers with hydrogen bonding or reversible ionic interactions and PU–acrylate coatings.10 They are reportedly being utilized for suppressing H-bonding, inducing phase segregation and tuning viscosity, crystallinity, and thermo-mechanical properties in renewable polyurethanes and polyamides and their biocomposites.14,15 More recently...
biobased fatty dimer diamines with long alkyl branches (Priamine) were reported as useful building blocks to develop room temperature self-healing polyimides with high mechanical properties.\textsuperscript{16,17} In that previous work we reported\textsuperscript{16} the effect of the stoichiometric offset of the ODPA/DD1 ratio on the dynamic mechanical and self-healing properties of the resulting polymers. However, the role of the dianhydride architecture on the overall properties of these fatty dimer diamine based...
Polymides were not examined, leaving room for further dedicated research.

Polymides are known for their capability of forming intramolecular and interchain electronic interactions called charge-transfer complexes (CTC), which are the reason behind their high thermo-mechanical properties and deep coloration. However, most of the aromatic polymides are insoluble in any organic solvent. That, in addition to very high transition temperatures, limits their usefulness for many applications. Flexible and bulky linkage groups are traditionally being introduced between aromatic rings in the dihydrazide monomer to enhance solubility, transparency, and processing. The goal of these modifications is to either disrupt their aromaticity (to prevent intramolecular conjugation) or to make the chains pack less efficiently (to prevent intermolecular CTC formation). Naturally, modification of the molecular architecture of PIs influences their mechanical properties and molecular dynamics as well.

In this work we report the effect of the aromatic dihydrazide structure on the thermal, optical, and mechanical properties and relaxation behavior of a set of polymides based on a biobased aliphatic dimer diamine (DD1). The results are discretized with regards to several aspects: planarity, rigidity, bridging group between the phtalimides, electronic properties, and the combinations thereof. Moreover, the effect of different physical constraints (crystal formation and electronic interactions) on the relaxation behavior is discussed in detail. Despite their partially aliphatic and densely branched architectures, it was found that the synthesized polymides are still able to form intermolecular charge transfer complexes, playing an important role in the overall properties of these semiamicronic thermoplastic polymides. To the best of our knowledge, this is the first time that the effect of fatty dimer diamine is explored in a set of different polymides with varying dihydrazide architecture.

## EXPERIMENTAL SECTION

### Synthesis

Four aromatic dihydrazides were used as hard aromatic block (Scheme 1): 4,4′-(4,4′-isopropylidenediphenopheno)-bis(phthalic anhydride) (BPADA; 97%, Sigma-Aldrich), 4,4′-oxiphthalic anhydride (ODPA; 98%, TCI Europe N.V.), 4,4′-(hexahydroisophthalidyne) diphthalic anhydride (6FDA; 98%, TCI Europe N.V.), 3,3,4,4′-biphenyltertcarboxyllic dihydrazide (BPDA; 98%, TCI Europe N.V.).

The soft block was in all cases a fatty dimer diamine derived from vegetable oil (Piramine 1075, here named DD1; Croda Nederland B.V.) with the structure as shown in Scheme 1. DD1 appears as a light yellow viscous liquid with melting point at −30 °C and 100% renewable carbon content. Theoretical stoichiometric ratios, calculated according to the molecular weights of the monomers (MWBPADA = 520.49 g/mol, MWODPA = 310.20 g/mol, MW6FDA = 444.24 g/mol, MWBPDA = 294.22 g/mol, and MWDD1 = 536.80 g/mol) and assuming conjugation) or to make the chains pack less efficiently (to prevent intermolecular CTC formation). Naturally, modification of the molecular architecture of PIs influences their mechanical properties and molecular dynamics as well.

To the best of our knowledge, this is the first time that the effect of fatty dimer diamine is explored in a set of different polymides with varying dihydrazide architecture.

## RESULTS AND DISCUSSION

### Effect of the Dianhydride Structure on the Polymides’ Properties

The imidization of PAA into PI can be confirmed by using a two-step polymerization process as described in Supporting Information (S-6).

**Broadband Dielectric Spectroscopy (BDS).** BDS measurements were performed on an ALPHA high resolution dielectric analyzer (Novocontrol Technologies GmbH). All samples were mounted in the dielectric cell between two parallel gold-plated electrodes. The complex permittivity ε′(ω) = ε′(ω) − u″(ω) of each sample was measured by performing consecutive isothermal frequency sweeps over a frequency window of 10^5 < f (Hz) < 10^10 (where f is the frequency of the applied electric field) in the temperature range from 0 to 100 °C in steps of 5 °C. The resulting relative error of each parameter is less than 3%.

**Tensile Properties.** Tensile mechanical tests were performed on an Instron model 3365 universal testing systems equipped with a 1 kN load cell, using dog-bone specimens according to the ASTM D1708 standard (thickness, t = 2 ± 0.5 mm) at 80 mm/min crosshead speed and ambient temperature (23 ± 2 °C).

**Fluorescence Spectroscopy.** The fluorescence spectra of polymides were obtained using a PTI QuantaMaster Photoluminescence Spectrometer equipped with 75 W Xe lamp and using a PMT voltage of 1000 V. The same specimen geometry as for the tensile test was used. First the excitation scan was run in the range 280–400 nm, collecting emission at 410 nm. From this, the fluorescence peak was determined at 360 nm. Further, the samples were excited at that particular wavelength and monitored over the range 370–700 nm using an aperture slit width of 2 nm with 1 nm step size and 0.1 s integration time during monitoring. Each measurement was repeated three times, showing good reproducibility. The sample thickness was found not to have an effect on the measured peak.
by IR spectroscopy using the disappearance of the amic acid peaks typically visible at 1716, 1640, and 1550 cm\(^{-1}\) in PAA spectra and the appearance of the characteristic peaks of imide bonds at 1770, 1710, 1360, and 745 cm\(^{-1}\) in PI spectra. The imidization reaction was confirmed for all of the polymers (Figure 1) and supported by \(^1\)H NMR analysis (Figure S1, Supporting Information). The percentage yields were calculated by the standard approach shown in the SI (Page S-2). Yields of 83\% for BPADA-D, 89\% for ODPA-D, 74\% for 6FDA-D, and 73\% for BPDA-D were obtained.

As can be seen from the TGA curves (Figure S2, Supporting Information), all polymers show a high thermal stability independent of the dianhydride architecture with values for the onset degradation temperature (2\% weight loss) at 330–380 °C (Table 1) similar to those of traditional commercial polyimides such as LaRC-IA. All samples showed only a small weight loss up to 0.6\% until 200 °C suggesting that almost no solvent (toluene or DMAc) was entrapped during the imidization and that the monomers were fully reacted. The resulting polymers were fully soluble in common organic solvents, such as toluene, THF, and chloroform, which facilitates their processing (for example, in coatings, adhesives and thin films applications), as opposed to commercial polyimides.\(^\text{19}\) The GPC results are presented in Table 1. The small differences in the molecular weights might be due to various reasons, such as impurities or side-reactions but also differences in the electron affinities of the aromatic dianhydrides. As the susceptibility of the nucelophilic attack increases with the electrophilicity of the dianhydride group, the reactivity of the dianhydride monomer is related to its electron affinity; higher values indicate higher reactivity of the dianhydride. According to the literature,\(^\text{18,26}\) the electron affinities of the dianhydrides used in this work increase in the order BPADA-D < ODPA-D < BPDA-D < 6FDA-D.

The flexibility of the dianhydride moieties is reflected in the value of the \(T_g\) where three polymers (BPADA-D, 6FDA-D, and BPDA-D) exhibit a similar \(T_g\) ranging from 22 to 25 °C and ODPA-D showing a lower value of 13 °C. The \(T_g\) values of these PIs are incomparable to those of fully aromatic commercial PIs (200 < \(T_g\) < 400 °C),\(^\text{27}\) which naturally excludes the possibility for their use in high-temperature applications. However, their \(T_g\)’s are higher than the ones of other reported polymers that contain fatty acid dimer as the building block that remained significantly below room temperature. The ionic supramolecular networks prepared from fatty acid dimer by Aboudzadeh et al. exhibit their \(T_g\)’s in the range –29 < \(T_g\) < 10 °C.\(^\text{10}\) The fatty acid dimer based polyamides from Hablot et al. showed –17 < \(T_g\) < –5 °C,\(^\text{12}\) while the values in the range –10 < \(T_g\) < –0.9 °C were obtained in the fatty acid dimer based polyamides synthesized by van Velthoven et al.\(^\text{13}\)

The ODPA and BPADA dianhydrides have a very flexible oxygen linker between the two phytic anhydride parts of the molecule (Scheme 1). Comprising two oxygen linkers, BPADA may appear the most flexible out of the four dianhydrides used here, yet it does not exhibit the lowest \(T_g\). This is likely to be caused by the increase in aromatic content compared to ODPA-D, where the extra flexibility of the ether linkage is counterbalanced by the increased number of aromatic rings. Despite the structural differences, BPDA-D and 6FDA-D display a similar \(T_g\). The expected increase in backbone flexibility of the 6FDA-D polymer may be compensated by the extra bulkiness of the CF3 groups. A similar effect of dianhydride structure on the \(T_g\) of nonbranched fully\(^\text{20}\) and partially aromatic\(^\text{28}\) polyimides was reported in the literature, with the exception of BPADA. A detailed DSC analysis (Figure S3, Supporting Information) shows the absence of melting or crystallization peaks thereby reflecting the amorphous nature of all of the polyimides in their state just after synthesis.

Rheological temperature sweeps were performed at a very slow cooling rate (1 °C/min), and the results are shown in Figure 2. Figure 2a shows the values of the storage modulus (\(G^\prime\)) and loss modulus (\(G^\prime\prime\)) while damping factors (\(\tan \delta\)) versus temperature at 1 Hz for all of the samples studied are shown in Figure 2b.

The differences between the \(T_g\) values determined from the maximum of the tan \(\delta\) peak (25 °C < \(T_g\) < 40 °C) arise from

Table 1. Effect of the DAi type on Mw, Mn, and PDI as Calculated from the Major Peak Obtained in GPC\(^\text{4}\)

| polymer   | Mw (g/mol) | Mn (g/mol) | PDI | DSC-\(T_g\) (°C) | rheology-\(T_g\) (°C) | BDS-\(T_g\) (°C) | TGA T (2% weight loss) (°C) | density (g/cm\(^3\)) |
|-----------|------------|------------|-----|-----------------|---------------------|-----------------|------------------------|-------------------|

\(^{4}\)\(T_g\) obtained from DSC, rheology, and BDS and temperatures for 2\% weight loss obtained from TGA. Samples were tested as produced. \(^{4}(\delta T_g\) was calculated from the 2nd heating curve, 10 °C/min. \(^{4}\)\(T_g\) was taken as the maximum of the peak in the tan \(\delta\) curve from the temperature sweeps, performed in cooling ramp, 1 °C/min. \(^{4}\)\(\delta T_g\) is obtained from the broadband dielectric spectroscopy (BDS) measurements, by extrapolating the VFT fit to the temperature at which \(\tau_{min}\) is equal to 100 s (see Figure S5, Supporting Information). \(^{4}\)Polymer BPDA-D exhibits two \(T_g\) peaks \([T_g (I) and T_g (II)]\) in rheological temperature sweep plots, which is shown and discussed later in the article.
the effect of different aromatic dianhydride structures on the glass transition processes. The width of the curves indicate the breadth of the temperature range over which the glass transition occurs but also the polymer structural heterogeneity.29 The values of tan δ of these polymers (especially BPADA-D and 6FDA-D with values close to 2) are remarkably high over a broad range of near-room temperatures, which makes them great candidates in applications where high damping properties are required at ambiental conditions (noise or vibration insulating materials, shock absorbers, and sealants). In general, damping materials with tan δ > 0.5 are considered for outdoor or machinery applications.30 (As seen in Figure 2b, BPADA-D and 6FDA-D are displaying the narrowest tan δ peaks. A somewhat broader curve was obtained with ODPA-D and the broadest with BPDA-D. Moreover, the BPDA-D system exhibits stepwise glass transition (shown in Figure 2b as (I) and (II)), as opposed to the other three (BPADA-D, ODPA-D, and 6FDA-D), which show single Tg.

Similar observations could be made from the broadband dielectric spectroscopy (BDS) data. The spectra corresponding to all four polymers over a wide range of frequencies at different temperatures are shown in Figure S4, Supporting Information. Tg was calculated from the temperature dependence of the segmental relaxation times (τmax). When this dependence follows a Vogel–Fulcher–Tammann (VFT) behavior, Tg is obtained by extrapolating the VFT fit to the temperature at which τmax is equal to 100 s (see the SI).31 The Tg’s calculated following this approach (Table 1) are similar to the values obtained by DSC and follow the same trend of increase among the four polymers investigated (ODPA-D < BPDA-D < BPADA-D < 6FDA-D), as seen by DSC and rheology. The temperature dependence of the relaxation times in the whole region of the segmental relaxation further supports the fact that the ODPA-D polymer has the least restricted dynamics (see the SI).

In addition to a third estimate of Tg, BDS gave some further insights on the structure and polymer architecture of the studied PIs.

By plotting the normalized dielectric loss vs normalized frequency, a clearer view on how the shape (symmetry and broadness) of the relaxation spectra varies is obtained. Figure 3 shows the normalized plots at a selected temperature (T = 50°C) at which the dielectric relaxation is clearly observable as a well-resolved peak in the frequency window for all polymers. Depending on the nature of the dianhydride incorporated into the polymer, clear differences in the shape of the spectra can be noticed. Schönhals and Schlosser32 phenomenological model proposes that the shape of the normalized dielectric loss peak is related to the behavior of the polymer at low and high frequencies, controlled by inter- and intramolecular interactions, respectively. The application of such a model to the studied polyimides suggests that the differences on the low frequency side may be related to the changes in the dynamics of the main chain segments due to the contribution/restriction imposed by the different dianhydrides, while the variations on the high frequency side can be attributed to the influence of the dangling side chains.

In order to quantify these differences, the dielectric strength (∆ε) and the shape parameters b and c derived from the Havriliak–Negami (HN) fitting function (see the SI) were calculated and shown in Figure 4. The b and c parameters characterize the symmetric and asymmetric broadening of the relaxation time distribution, respectively. The term b*c is also shown in the same figure. In a log(ε″) vs log(ƒ) plot, just as in Figure 3, the shape parameters b and b*c correspond to the low- and high-frequency slopes of the relaxation function respectively, with regards to the position of the maximal loss.33

A detailed analysis of the plots in Figure 4 gives better insight into the effect of different dianhydrides on the resulting polymer architectures. An increase in dielectric strength (∆ε) can be understood in terms of an increasing number of mobile dipoles (increasing fraction of polar molecules) involved in the relaxation, indirectly reflecting stronger molecular interactions.
We can therefore infer that the BPADA-D system has higher dipole interactions than the rest of the PI systems with other dianhydrides. Recently, research on the relaxation behavior of thermo-reversible elastomer networks based on 2-ureido-4-pyrimidinone (UPy) dimers has been published by Luo et al.34 In their work they report on the appearance of a new relaxation, seen as a shoulder close to the segmental relaxation, ascribed to the dissociation dynamics of dimer complexes within the network. They conclude that this new relaxation is related to the local UPy dimers dynamics resulting from the dissociation and reformation of the complexes. They also report an increase of $\Delta \varepsilon$ due to the increased number of dissociated UPy units. In our work, there is no evidence of a new relaxation probably because they take place within the temperature range within the glass transition; therefore, any weaker relaxation is hidden by the strong segmental relaxation.

Second, the fact that the $b$ parameter is higher for the BPADA-D system reflects a narrower and more symmetrical loss peak. In terms of the polymer architecture, this would suggest a more homogeneous structure formed by polymer chains with similar large scale motions. On the contrary, the lowest $b$ value for the BPDA-D system suggests chain segments with different dynamics and thus a higher degree of structural heterogeneity, implying regions of distinct mobility. This hypothesis is confirmed by the presence of a stepwise glass transition, as reported by rheological measurements (Figure 2b). Moreover, the lowest $b^*c$ parameter for BPDA-D is further confirming heterogeneous dynamics of this sample with a more visible temperature dependence. As the temperature increases, the $b^*c$ parameter tends to increase, presuming the distinct heterogeneous mobility regions become more homogeneous, especially above 50 °C. As will be discussed later on, the increase on $b^*c$ values above 50 °C could be related to local

ordering present in the BPDA-D sample appearing at around 50 °C. Aromatic polyimides are well-known for forming charge transfer complexes (CTCs), which are widely claimed to be the reason behind their great mechanical and thermal properties, as well as their characteristic colors,18 due to their absorption characteristics tailing in the visible region caused by the intra and/or intermolecular charge transfer (CT) interactions of the PI backbones. Moreover, CTCs have a major effect on the chain packing.27,35 In order to investigate the origin of the different coloration, the polymer optical properties were tested by fluorescence spectroscopy as typically used in polyimide research to identify the formation of CTCs.18,33−39 The CTCs existence has been previously confirmed for not only fully aromatic PIs but also in the semiaromatic ones.40 Our results showed that CTCs in the branched polyimides are identified by a long-wavelength absorption at λ > 330 nm, similar to those reported in literature.37,38 As can be seen in Figure S, the four polyimides developed in this work are fluorescent in the CTC-region (400 nm < λem < 450 nm).

**Effect of the Low Temperature Annealing on Local Ordering.** Another important factor affecting the physical properties of polyimides is the aggregation state of polymer chains, i.e., macromolecular packing. Many have shown that imidization temperature affects the aggregation state of PIs,38 but the postimidization thermal treatment (i.e., annealing) does as well.41 In order to further explore the origin of physical constraints on the properties of the given set of DD1 based PIs, they were subjected to low temperature annealing, Tann = T(tan δMAX) = Tg (see Table 2), for 1, 5, and 11 days. Their thermal, optical, and mechanical properties were then evaluated as a function of the annealing time. The DSC scans of all four polymers show no change in their Tg values. However, as opposed to the other three polymers, a change in opacity with time was noticed for BPDA-D, turning from translucent to fully turbid after 5 and 11 days at Tann. DSC scans of turbid BPDA-D show an appearance of a melting peak at 68 °C (yet no change in the Tg value). The melt enthalpy increases from 5 J/g (for 5 days annealed) to 11 J/g (for 11 days annealed) with no change in Tm (Figure 6). As seen by polarized microscopy (Figure S7, Supporting Information), the birefringence increases with annealing time as well. These observations can be explained by the rigidity and planarity of the BPDA monomer which result in the chain regularity and hence efficient chain packing, allowing the BPDA-D polymer to crystallize.28 At this stage it is not possible to unambiguously state which segments of the molecule crystallize. Nevertheless, the increase of order in chain packing with annealing time in BPDA-D polymer was confirmed by small-angle X-ray scattering measurements, SAXS (Figure S8, Supporting Information) by the appearance of two additional peaks at annealing times 5 and 11 days, with respect to 1 day. The peak ratio is q1:q2:q3 = 1:2:3, which was previously reported to be related to the nanophase separation in lamellar morphology.42 Taking in account that Tm is rather low (68 °C) and considering reported similar range of Tm values for other partially aromatic polymers with alkyl side branches in the literature,43,44 we suggest that crystals might be formed within

![Figure 6](https://example.com/figure6.png)

**Figure 6.** (a) DSC traces from the second heating curve with Tg and Tm indicated by the dashed lines and (b) corresponding images showing increase in opacity of BPDA-D polymer with annealing time. Tann = T(tan δMAX) = Tg.

**Figure 7.** Rheological T-sweep curves. Effect of annealing on the glass transition relaxation behavior of the BPDA-D polymer. Red curve represents the nonannealed polymer and the blue curve shows the polymer annealed for 11 days at Tann = T(tan δMAX) = Tg.
the nanodomains of the alkyl side branches. As Beiner and Huth suggested, this may be a result of a confinement of the alkyl side chains by less-mobile main chains. However, further research is necessary to confirm this hypothesis.

On the contrary, the polymers with the other three dianhydrides remain fully amorphous with the annealing time. Even though rigid, the bulky hexafluoroisopropylidene spacer of 6FDA dianhydride causes distortions of backbone symmetry which prevents the parallel alignment of the chains. On the other hand, the ether linkages of BPADA and ODPA are not bulky but offer high rotational freedom and flexibility which reduces the rigidity of the backbone, introduces kinks which hinder the coplanarity and thus prevent efficient chain packing. The same dianhydride effect on crystallization ability was noticed in fully aromatic rigid rod polyimides and copolyimides, comprising various diamines. For example, Arnold et al. prepared nine polyimides using six different dianhydrides, including ODPA, 6FDA, and BPDA among others. Only two polymers with different diamines were able to crystallize during drawing or and annealing and both of them comprised BPDA as the dianhydride.

While the rheological temperature sweeps of the polymers BPADA-D, ODPA-D, and 6FDA-D do not show any change with the annealing time, the BPDA-D polymer undergoes significant change in the glass transition region, as can be seen in Figure 7.

After 11 days of annealing, the tan δ decreases over the whole range of temperatures tested. Furthermore, the curve broadens and the two peaks are less pronounced, which is expected, as the content of the amorphous phase decreases with the increase in the crystalline fraction. This multiple-Tg relaxation behavior is characteristic for multiphase structures and incompatible blends. However, the behavior noticed in the BPDA-D polymer is peculiar because of the (consistently) reverse magnitudes of the two peaks (Tg(I), at the lower temperature and Tg(II), at the higher temperature). This can be expressed in terms of activation energies as well. Activation energies, Ea, are calculated from the Arrhenius plots (Figure S6, Supporting Information), as described in the Supporting Information. The peak at the lower temperature, Tg(I), exhibits higher Ea than the one at higher temperature, Tg(II) (see Table S1, Supporting Information). Such an observation can be explained by assuming a less mobile phase present at the crystal–amorphous phase interface. Thus, based on the literature and the DSC evidence that the BPDA-D polymer is the only semicrystalline (Figure 6) polymer out of the four here investigated, we could explain the multiple tan δ peaks as follows: the relaxation occurring at about 33 °C is presumed to be the relaxation of the major part of the amorphous phase, a Tg per se. The relaxation occurring at a higher temperature of 46 °C can be attributed to the restricted amorphous phase located in the interfacial region.

The effect of the aromatic dianhydride architecture on the mechanical properties was also evaluated. Figure 8 shows...
representative strain–stress curves of the four PIs obtained at ambient temperature ($T_{\text{test}} = 23 \pm 2$ °C). The mechanical performance changes significantly with varying the dianhydride architecture. ODPA-D polymer shows elastomeric behavior, which is as expected because its $T_g$ is below $T_{\text{test}}$ as opposed to the other three polymers that are in their glassy state ($T_g > T_{\text{test}}$).

The stress at break values ($\sigma_b$) increase in the order ODPA-D < BPADA-D < BPDA-D < 6FDA-D and the strain at break ($\epsilon_b$) values in the following order BPADA-D < 6FDA-D < BPDA-D < ODPA-D. The 6FDA-D system shows the highest toughness and strain hardening while BPADA-D exhibits strain softening, having yield stress higher than its stress at break value. Young’s moduli are in a broad range, from 90 MPa (ODPA-D) to 430 MPa (6FDA-D), comparable to the fatty acid dimer based polyamides of Hablot et al. When compared to commercial fully aromatic PIs, these materials are roughly 1 order of magnitude lower in strength.

The effect of annealing on the tensile properties is also shown in Figure 8. The three amorphous polymers (BPADA-D, ODPA-D, and 6FDA-D) show minor improvement of the mechanical properties with annealing time, while the effect on the semicrystalline BPDA-D is more evident. The stress at break value increases from 11 to 20 MPa, and the strain at break value decreases from 260% to 35%, despite the nonrelevant variation in $T_g$. The repeated fluorescence spectra after annealing the samples did not show any shifts in fluorescence peaks wavelengths.

CONCLUSIONS

A series of partially bio based semiaromatic polyimides varying in their aromatic dianhydride structure was synthesized in stoichiometric ratio with the fatty dimer diamine and their thermal, mechanical, and optical properties were investigated. The polymers obtained were fully organo-soluble thermoplastic branched polyimides with glass transition temperatures close to room temperature. Their solubility, amorphous thermoplasticity, and high thermal stability makes them easily processable and recyclable without deterioration of mechanical properties. The results have shown that the dianhydrides comprising a flexible ether spacer (BPADA and ODPA), as well as the one with rigid and bulky hexafluoroisopropylidene spacer (6FDA), yielded fully amorphous polymers. However, the dianhydride with no spacer (BPDA) provided a semicrystalline polymer structure with the annealing time, which lead to a constrained segmental relaxation. Despite their partially aliphatic and densely branched architectures, these polyimides were able to form the intermolecular charge transfer complexes, whose extent was dependent on the dianhydride electronic properties and evident from their fluorescence spectra and normalized dielectric loss. The increase in crystallinity with annealing time was shown to have a great effect on the tensile properties of the BPDA-D polymer despite no significant $T_g$ variation was measured. The values of tan $\delta$ of these polymers (especially BPADA-D and 6FDA-D with values close to 2) were remarkably high over a broad range of near-room temperatures, which makes them great candidates in applications where high damping properties are required at ambient conditions (noise or vibration insulating materials, shock absorbers, and sealants).
