MIGHT WE EVENTUALLY UNDERSTAND THE ORIGIN OF THE DARK MATTER VELOCITY ANISOTROPY?

ABSTRACT

The density profile of simulated dark matter structures is fairly well-established, and several explanations for its characteristics have been put forward. In contrast, the radial variation of the velocity anisotropy has still not been explained. We suggest a very simple origin, based on the shapes of the velocity distribution functions, which are shown to differ between the radial and tangential directions. This allows us to derive a radial variation of the anisotropy profile which is in good agreement with both simulations and observations. One of the consequences of this suggestion is that the velocity anisotropy is entirely determined once the density profile is known. We demonstrate how this explains the origin of the $\gamma - \beta$ relation, which is the connection between the slope of the density profile and the velocity anisotropy. These findings provide us with a powerful tool, which allows us to close the Jeans equations.

1. INTRODUCTION

The natural outcome of cosmological structure formation theory is equilibrated dark matter (DM) structures. According to numerical simulations, the mass density profile, $\rho(r)$, of these structures changes from something with a fairly shallow profile in the central region, $\gamma \equiv d\ln \rho/d\ln r \sim -1$ (or maybe zero), to something steeper in the outer region, $\gamma \sim -3$ (or maybe steeper) (Navarro et al. 1996; Moore et al. 1998; Diemand et al. 2004) (see also Reed et al. 2003; Stoehr 2004; Navarro et al. 2004; Graham et al. 2006; Merritt et al. 2006; Ascasibar & Gottloeber 2008; Stadel et al. 2008; Navarro et al. 2008). For the largest structures, like galaxy clusters, there appears to be a fair agreement between the numerical predictions and observations concerning the central steepness (Pointecouteau et al. 2005; Sand et al. 2004; Buote & Lewis 2004; Broadhurst et al. 2005; Vikhlinin et al. 2006), however, for smaller structures, like galaxies or dwarf galaxies, observations tend to indicate central cores (Salucci et al. 2003; Gilmore et al. 2007; Wilkinson et al. 2004) (see also Rubin et al. 1985; Courteau 1997; Palunas & Williams 2000; de Blok et al. 2001; de Blok, Bosma & McGaugh 2003; Salucci 2001; Swaters et al. 2002; Corbelli 2003; Salucci et al. 2007). The various theoretical approaches still make different predictions (Taylor & Navarro 2001; Hansen 2004; Austin et al. 2005; Dehnen & McLaughlin 2005; González-Casado et al. 2007; Henriksen 2007, 2009), varying from central cores to cusps.

The second natural quantity to consider (after the density profile) is the velocity anisotropy, which is defined through

$$\beta \equiv 1 - \frac{\sigma^2_t}{\sigma^2_r}, \quad (1)$$

where $\sigma^2_t$ and $\sigma^2_r$ are the one-dimensional tangential and radial velocity dispersions (Binney & Tremaine 1987). If most dark matter particles in an equilibrated structure were purely on radial orbits, then $\beta$ could be as large as 1, and for mainly tangential orbits $\beta$ could be arbitrarily large and negative. Since dark matter is collisionless $\beta$ does not have to be zero, and it could in principle even vary as a function of radius.

Numerical N-body simulations of collisionless dark matter particles show that the dark matter velocity anisotropy is indeed radially varying, and that $\beta$ goes from roughly zero in the central region, to 0.5 toward the outer region (Cole & Lacey 1996; Carlberg et al. 1997). Only very recently has this velocity anisotropy been measured to be nonzero in galaxy clusters (Hansen & Piffaretti 2007), and it has even been observed to be increasing as a function of radius (Host et al. 2009), in excellent agreement with the numerical predictions. For smaller structures, like our own galaxy, this has not been observed yet. In principle $\beta$ of our Galaxy can be measured in an underground directional sensitive detector, however, it will require a large dedicated experimental programme (Host & Hansen 2007). Very little theoretical understanding of the origin of this velocity anisotropy exists, and to my knowledge no successful derivation of it has been published (see, however, Hansen & Moore 2006; Salvador-Sole et al. 2007; Wojtak et al. 2008). We will in this paper present an attempt toward deriving $\beta$.

2. DECOMPOSITION

When analyzing the outcome of a numerically simulated dark matter structure one traditionally divides the equilibrated structure in bins (shells) in radius, or in potential energy. For spherical structures there is naturally no difference. We can now consider all the particles in a given radial bin, and calculate properties such as average density, angular momentum, velocity anisotropy, etc. In order to do this, we must decompose the velocity of each particle into the radial component, and the two tangential components. The two tangential components can for instance be separated according to the total angular momentum of all the particles in the bin.

By summing over all the particles in the radial (or potential) bin, we thus get the velocity distribution function (VDF), which for a gas would have been a Gaussian represented by the local gas temperature, $f(v) \sim \exp(-E/T)$. We are here discussing the one-dimensional VDF (i.e., the one where the two other velocities are integrated over), and we are not assuming that the radial and tangential VDFs are independent. Naturally, since dark matter particles are not collisional, the concept of temperature is not well defined for them. In numerically simulated
structures one observes that the radial VDF is symmetric (with respect to particles moving in or out of the structure), and also the nonrotational part of the tangential VDF is symmetric. The asymmetry of the rotational part of the tangential VDF was discussed in Schmidt et al. (2009) for the DM particles. For the structures with very little rotation, the two tangential VDFs are virtually identical. To avoid any complications from the total angular momentum we will hereafter only discuss the two symmetric one-dimensional VDFs. For any given radial bin in a given DM structure, the shape of the VDF only depends on the momentaneous distribution of particles (which should be virtually time-independent for equilibrated structures), and is independent of the method by which the structure is selected.

When analyzing dark matter structures resulting from cosmological simulations, we find that the shape of the radial VDF changes as a function of radius (Wojtak et al. 2005; Hansen et al. 2006; Faltenbacher & Diemand 2006; Fairbairn & Schwetz 2009). In particular, the bins in the inner region tend to have long tails (more particles at high velocity compared to a Gaussian), whereas bins at larger radii tend to have stronger reduction in high velocity particles. This is exemplified in Figure 1, where the upper curves (blue and green) show the radial VDF. The open diamonds (blue) come from a radial bin in the inner region, whereas the stars (green) are from a bin further out. The VDFs are normalized such that a comparison is possible, and velocity is normalized to the dispersion. These simulated cosmological data are from the Local Group simulation of Moore et al. (2001).

The lower curves (red and black) are the tangential VDF from the same two bins, however, for the tangential VDF there is a striking resemblance, in fact to a first approximation these two tangential VDFs from different radial bins look identical.

The most frequently used approach to discuss DM structures is through the first Jeans equation, which relates the velocity dispersions to the density profiles. If we were to have some knowledge about some of the quantities entering the Jeans equation, then we can solve for the others. One example hereof was presented in Dehnen & McLaughlin (2005), who demonstrated how to derive a generalized Navarro–Frenk–White (NFW) density profile, by both assuming that the pseudo phase space is a power law in radius (Taylor & Navarro 2001), and that there is a linear relation between the velocity anisotropy and the density slope (Hansen & Moore 2006). A somewhat generalized approach was presented in Zait et al. (2008), where the authors demonstrated how to derive the velocity anisotropy by assuming simple forms for both the density profile and the pseudo phase-space density. The fundamental problem with these kinds of approaches is that any departure from truth in the assumptions will lead to departure from correctness in the results. Zait et al. (2008) demonstrated this in a very convincing way, by deriving significantly different velocity anisotropy profiles by just changing between NFW or Sersic density profiles as input. Another related problem with these approaches is that the assumption that pseudo phase space is a simple power law has recently been demonstrated to be oversimplified. The unknown question was which component (radial, tangential, or something else) of the velocity dispersion in the pseudo phase space gives the best approximation to a power law in radius (Hansen et al. 2006; Knollmann et al. 2008).

Schmidt et al. (2008) demonstrated that different numerically simulated structures are best fitted by different forms of the pseudo phase space, and hence that there is no universal simple behavior of the pseudo phase space.

2.1. The Shape of the Radial VDF

For ergodic structures, that is structures where the orbits depend only on energy (hence with $\beta = 0$) we can use the Eddington formula to get the VDF at any radius (Eddington 1916) (see also Binney 1982; Cuddeford 1991; Evans & An 2006). The Eddington formula only depends on the radial dependence of the density profile of the structure, and by assumption the VDF is the same for the radial and tangential directions, $f(v, r) = \text{function}(\rho(r))$. It is natural to interpret this in the following way. The structure is in equilibrium, so there is detailed balance for each phase-space element. The velocity of each particle is decomposed into the radial and tangential components, and for any infinitesimal time step, the radial component of any individual particle can tell that it is moving in a changing density and changing potential (the radial component of any individual particle is either moving directly inward or outward). It is therefore natural that the radial VDF is imprinted by the radial variation in the density and potential.

For a truncated NFW density profile we can, e.g., get the VDF at radii 0.1 and 10, in units of the characteristic radius, see Figure 2. By comparison of Figures 1 and 2 it is clear that the radial VDF of the cosmological simulation indeed looks very similar to the VDF from the Eddington formula. It is therefore tempting to suggest that the radial VDF to a first approximation is identical to that which results when applying the Eddington formula to the given density profile.

Now, the actual radial VDF (for a given cosmologically simulated structure) will differ slightly from the VDF resulting from the Eddington formula, since the latter was based on the assumption that $\beta = 0$. Specifically, the VDF from the Eddington formula also gives $\sigma_r$, and to ensure consistency with the Jeans equation, one must have $\beta = 0$. However, we will here use this VDF as a first approximation to the radial VDF, and we will present a quantitative comparison in a future paper. Recently, Van Hese et al. (2009) showed that for a large class of theoretical models, this is an excellent approximation (see their Figure 5).
Figure 2. Velocity distribution function for two different radial bins from the Eddington formula for an NFW density profile. The open diamonds are from an inner bin ($r = 0.1$), and stars are from an outer bin ($r = 10$). There is a striking resemblance with the radial VDFs from the cosmological simulation in the upper curves in Figure 1. Same normalization as Figure 1. (A color version of this figure is available in the online journal.)

2.2. The Shape of the Tangential VDF

It is somewhat less trivial to argue (or claim) the shape of the tangential VDF. For an infinitesimal time step, the tangential component of any individual particle’s velocity moves in constant density and constant potential (the tangential velocity component of any individual particle moves, well, tangentially, and we assume spherical symmetry). We still assume that the structure is in equilibrium with no time variation. This means that as a first approximation the tangential VDF can be thought of as that resulting from an infinite and homogeneous medium, where both the density and potential are constant everywhere. This argument is similar to the Jeans swindle, where the homogeneous medium implies constant potential. Naturally, such an infinite structure is not gravitationally stable against perturbations, but we can instead approximate it in the following way.

Let us consider a density profile, which is a power law in radius over many orders of magnitude, and is then truncated. One example hereof is an NFW profile, where the central density slope is $-1$, and the corresponding truncation is then happening after the scale radius. We are thus considering the VDF in a bin at a radius which is many orders of magnitude deeper toward the center than the scale radius. We can now consider a generalized double power-law profile, where the central slope can be more shallow than $-1$, and we can use the Eddington formula to extract the VDF for any central slope. By lowering the central slope toward zero, we get a structure which in principle is stable toward perturbations, but at the same time is approaching constant density and constant potential in the central region. The resulting VDF (extrapolated to zero slope) has been discussed by Hansen et al. (2005) and has the shape

$$f(v) = n(\rho) \left(1 - \frac{1 - q}{3 - q} \left(\frac{\nu}{\sigma}\right)^2\right)^{\frac{1}{3q}}, \quad (2)$$

with $q = 5/3$, and $n(\rho)$ shows that the normalization only depends on the local density. This form is known as a $q$-generalized exponential (Tsallis 1988). For comparison, one should note that a simple comparison with polytropes (where $f(E) \sim E^{(\alpha - 3/2)}$) breaks down since the normal connection between density and potential, $\rho \sim \Psi^n$, is not valid for such shallow slopes (Binney & Tremaine 1987).

When considering the shape of the tangential VDF from simulations in Figures 3 and 4 we see that this form indeed provides a very good fit for all radii, at least for $\nu$ smaller than roughly $2\sigma$. The structure in Figures 3 and 4 is from a very noncosmological simulation (the “tangential orbit instability” of Hansen et al. 2006). The same form fits the tangential VDFs from a cosmological simulation (lower lines in Figure 1) equally well.

Clearly, this form in Equation (2) has an extended tail of high-energy particles, which would not be bound by the equilibrated structure. The suppression of high-energy particles due to the finite radial extent of the structure is naturally included through the Eddington formula for the radial component, and we therefore make the suggestion that the tangential VDF must have a high-energy tail which follows the radial VDF. Effectively, this means that for large velocities the tangential component of the velocity might as well be moving in the radial direction. This
corresponds to the fact that the tangential velocity component of any individual particle actually is moving somewhat radially after a finite time interval.

When looking at Figure 4 we see that the actual suppression is even slightly larger for these high-energy particles, however, the difference between the suggested and the actual suppression at high energy is very small. When looking at the number of particles (the integral under the curve in Figure 3) we find that the difference is virtually zero.

In conclusion, the tangential VDF is surprisingly well fitted by the phenomenologically predicted shape in Equation (2), and with a high-energy tail suppression corresponding to the tail of the radial VDF.

To emphasize the general nature of the shape of the tangential VDF, we also present the radial and tangential VDFs of a cosmological simulation of a galaxy, including both cooling gas, star formation and stars, as well as supernova feedback from Sommer-Larsen et al. (2003) and Sommer-Larsen (2006). In Figure 5 we see that the dark matter VDF also in this case has the suggested shape.

3. THE VELOCITY ANISOTROPY

Now, after having established the shape of both the radial and tangential VDFs, the velocity anisotropy at any given radius can easily be determined, as we will show later in this section, since it is just an integral over these distributions, \( \sigma^2 = \int v^2 f(v) dv / \int f(v) dv \). The shape of the radial VDF changes as a function of radius (Section 2.1), whereas the shape of the tangential VDF is virtually constant (Section 2.2), and it is therefore natural to expect that the velocity anisotropy will also change as a function of radius. Since the radial VDF generally is more flat-topped than the tangential one (see Figure 4, top lines), we will expect \( \beta \) to be positive. Only when the density slope approaches zero (e.g., a central core) will the radial VDF approach the tangential one, and hence \( \beta \rightarrow 0 \) (see Figure 4, bottom lines).

Let us assume that the radial density profile is given, e.g., by a truncated NFW profile. In this case the radial VDF is completely determined through the Eddington formula. The tangential VDF is given by Equation (2) and at first sight there are two free parameters, namely the \( \sigma \) entering Equation (2), and then the normalization. For a given \( \sigma \) we can determine the normalization, since the particle number is conserved when integrating over the radial or tangential VDF, \( \int f_{\text{rad}} dv = \rho = \int f_{\text{tan}} dv \). This leaves us only to determine the \( \sigma \) entering Equation (2). One could argue that it most likely is either \( \sigma_{\text{r}} \), \( \sigma_{\text{tan}} \), or \( \sigma_{\text{tot}} \) which should enter here. We will allow ourselves to be guided by the results of numerical simulations, and use the average \( \sigma_{\text{tot}} \), since that gives a fairly good approximation to all the tangential VDFs from the simulations discussed above. We will present a more quantitative test of this in a future paper, but the effect is modest. For example, for the truncated NFW profile at the radius where the slope is \(-2\), we find \( \beta = 0.265 \) when using \( \sigma = \sigma_{\text{tot}} \), and if we instead use \( \sigma = \sigma_r (\sigma_{\text{tan}}) \) we get \( \beta = 0.22(0.31) \).

It is now straightforward to calculate the velocity anisotropy, \( \beta \), at any radius for any given density profile with no free parameters. Practically, we do it iteratively in the following way. (1) We find the radial VDF using the Eddington formula. (2) We write the tangential VDF that is Equation (2) where we initially use \( \sigma = \sigma_r \) (initially assuming \( \beta \) to be very small). (3) We then replace this form at high momenta with the radial VDF (as described in detail in Section 2), and normalize in such a way that the particle number is conserved between radial and tangential. (4) It is now trivial to calculate \( \beta \) as an integral over these distribution functions, and if this is different from the initial assumption, then reiterate the entire process with the calculated \( \beta \). This means explicitly that we return to (2) with this newly calculated \( \beta \), and \( \sigma = \sigma_{\text{tot}} \). In practice, we repeat until \( \beta \) has converged with accuracy 0.01.

In Figure 6 we present the radial dependence of \( \beta \) for three density profiles, namely an NFW profile with a truncation at large radius, a profile such as that advocated by Navarro et al. (2004), and finally a profile of the form \( \rho(r) \sim 1/(1 + r^2)^{3/2} \), which has a central core. We see that the anisotropy increases in a way similar to that observed in numerical simulations, namely from something small in the central region to something of the order 0.4 toward the outer region. The orange squares
are from CLEF numerical simulation (Kay et al. 2007; Springel 2005), where the error bars represent the 1σ scatter over the 67 most relaxed clusters (Host et al. 2009). Observations of β(r) in galaxy clusters are in excellent agreement with these numerical predictions (Host et al. 2009). The radial scale of the simulated β is r_{2500}, which does not have to coincide with the scale radius of the analytical profiles. This gives a free parameter (of the order unity) in the normalization of the x-axis, which we just put to 1 for simplicity. In a similar way the analytical profiles are all normalized to their respective scale radii, which means that they could also have different r_{2500}.

Since we have suggested the shape of the full VDFs, then we can naturally also get higher-order moments, such as the kurtosis, as a function of radius. In a similar way the analytical profiles are all normalized to their respective scale radii, which means that they could also have different r_{2500}.

4. DISCUSSION

One of the consequences of the above considerations is that the appearance of the radial variation of β is dictated by the density profile. That is, given any density profile, the velocity anisotropy is entirely determined, as long as the structure has had time to equilibrate. We are thus stating explicitly that the anisotropy and the slope of the density profile should exist. This connection appears to hold even for structures that have profiles with nontrivial radial variation in dlnρ/dlnr (Hansen & Stadel 2006). We can now test this connection. In Figure 7 we show β as a function of the density slope for the NFW profile (solid line, blue triangles), the profile suggested by Navarro et al. (2004) (red diamonds), and also for a “double-bump” structure (the sum of two spatially separated profiles of the form 1/(1+r)^3, orange squares). This double-bump profile has a nontrivial radial variation of dlnρ/dlnr, which cannot be well approximated by any generalized double power-law profile. All these structures appear to land near a connection roughly given by β = −0.13γ. We also show the results for the ρ = 1/(1+r)^2 profile (green stars), and single power-law profiles (fat black line, crosses). The dashed line is β = −0.2(γ−0.8) as suggested in Hansen & Stadel (2006), based on a set of cosmological and noncosmological simulations. These two results differ by approximately 0.1 in β. We indeed see that all structures land in a relatively narrowband in the γ–β plane, and hence likely explaining the origin of the γ–β relations.

The most important practical implication of this suggestion is that it will allow us to close the Jeans equation. As is well known, the Jeans equation depends on the density, dispersion, anisotropy, and the total mass. Now, having demonstrated (or at least suggested strongly) that the anisotropy is uniquely determined once the density is known, we see that it is possible to close the Jeans equation for systems that are fully relaxed.

We have been making simplifying assumptions above, all of which need to be tested through high-resolution simulations. First, we assume that the radial VDF is very similar to that appearing from the Eddington formula, even in the presence of a nonzero β. We also assume that the σ entering Equation (2) is the total one. If the correct σ to use is instead closer to σ_{tan}, then β will be slightly larger, but the radial variation will remain.

From these assumptions we estimate the accuracy of the present work to be about 0.1 or up to about 30% in β(r).

One could naturally ask why and how the radial and tangential VDFs get their shapes? It is slightly disappointing that it is not a deep physical principle, such as generalized entropy, which is responsible. Instead it is simply the density profile (either the radially varying, or the tangentially constant) that through the Eddington formula demands that the VDFs take on these forms. These forms will therefore appear when there is sufficient amount of violent relaxation to allow enough energy exchange between the particles.

5. SUMMARY

The velocity of any particle can be decomposed into the radial and tangential components, and when summing over all particles in a radial bin, we get the particle velocity distribution function, the VDF. We suggest that both the radial and tangential VDFs are given through the Eddington formula. The radial one comes from the radially changing density profile, and the
tangential VDF arises when considering a structure with constant density and potential. This is because the tangential component of the velocity of any individual particle as a first approximation moves in constant density and constant potential. In addition, the tangential VDF is reduced for high-energy particles in accordance with the radial VDF, to ensure that the particles remain bound to the structure. These phenomenological predictions are in remarkably good agreement with the results from numerical simulations of collisionless particles, both structures of cosmological origin and highly noncosmological origin.

Under these suggestions it is straightforward to derive the velocity anisotropy profile, $\beta(r)$, with no free parameters. This is shown to increase radially from something small (possibly zero) in the center, to something large and positive (possibly around 0.4) toward the outer region.

We have thus demonstrated that the velocity anisotropy is entirely determined from the density profile. This allows us to close the Jeans equation, since $\beta$ is no longer a free parameter.

It is a pleasure to thank Jin An and Ole Host for discussions, and Ben Moore and Jesper Sommer-Larsen for kindly letting me use their simulations. I also thank the anonymous referee for critical questions that improved the presentation. The Dark Cosmology Centre is funded by the Danish National Research Foundation.
