A Protein Profile of Visceral Adipose Tissues Linked to Early Pathogenesis of Type 2 Diabetes Mellitus*§

Su-Jin Kim‡§¶, Sehyun Chae¶||, Hokeun Kim‡, Dong-Gi Mun‡, Seunghoon Back‡, Hye Yeon Choi**, Kyong Soo Park‡‡, Daehee Hwang§§, Sung Hee Choi**§§, and Sang-Won Lee‡‡‡

Adipose tissue is increasingly recognized as an endocrine organ playing important pathophysiological roles in metabolic abnormalities, such as obesity, cardiovascular disease, and type 2 diabetes mellitus (T2DM). In particular, visceral adipose tissue (VAT), as opposed to subcutaneous adipose tissue, is closely linked to the pathogenesis of insulin resistance and T2DM. Despite the importance of VAT, its molecular signatures related to the pathogenesis of T2DM have not been systematically explored. Here, we present comprehensive proteomic analysis of VAT samples in drug-naive early T2DM patients and subjects with normal glucose tolerance. A total of 4,707 proteins were identified in LC-MS/MS experiments. Among them, 444 increased in abundance in T2DM and 328 decreased. They are involved in T2DM-related processes including inflammatory responses, peroxisome proliferator-activated receptor signaling, oxidative phosphorylation, fatty acid oxidation, and glucose metabolism. Of these proteins, we selected 11 VAT proteins that can represent alteration in early T2DM patients. Among them, up-regulation of FABP4, C1QA, S100A8, and SORBS1 and down-regulation of ACADL and PLIN4 were confirmed in VAT samples of independent early T2DM patients using Western blot. In summary, our profiling provided a comprehensive basis for understanding the link of a protein profile of VAT to early pathogenesis of T2DM. Molecular & Cellular Proteomics 13: 10.1074/mcp.M113.035501, 811–822, 2014.

Adipose tissue is a complex endocrine organ in which mature adipocytes coexist with connective tissue matrix, immune cells, the stromal vascular fraction of cells, and blood vessels (1, 2). The different fat depots, such as visceral adipose tissue (VAT) and subcutaneous adipose tissue (SAT), release different types of adipokines and have distinct responses to hormones or mitochondrial density (3–5). In particular, VATs located in intra-abdominal cavities and around internal organs (1, 4, 6) release adipokines and free fatty acids (5, 7–9), thereby influencing the physiology of other organs (e.g. liver, pancreas, brain, or muscle). For example, the adipokines released from VATs regulate lipid metabolism in liver (10, 11). Thus, alterations in VATs lead to metabolic disorders with systemic inflammation, including atherosclerosis, obesity, dyslipidemia, cardiovascular disease, insulin resistance, type 2 diabetes mellitus (T2DM), and hypertension (7, 8, 12–15).

In patients with T2DM, the accumulation of visceral fat has been reported to have a high correlation with peripheral insulin resistance, especially hepatic insulin resistance (13, 16). Moreover, higher amounts of VATs are commonly observed in patients with metabolic diseases and other ectopic fat deposition (13, 17). The alteration in the metabolic milieu and adipokine secretion of VATs in patients with insulin resistance

and T2DM relative to healthy controls has been considered as important pathophysiology for developing T2DM and cardiovascular disease (13, 15). Thus, these data suggest that VATs can serve as a key target organ from which novel molecules or pathways linked to the pathogenesis of T2DM, cardiovascular disease, or obesity can be identified.

The search for novel proteins or pathways linked to complex human diseases has been facilitated by the use of proteomic technologies. Several proteomic studies have provided global proteome profiles of tissue and serum samples from T2DM patients or mouse models and identified protein profiles associated with the pathogenesis of T2DM (18–22). For example, Li et al. (18) identified 68 proteins elevated in the sera of T2DM patients and found that the complement system is significantly associated with T2DM. Among the 68 proteins, they further validated ficolin-3, an upstream activator of the complement pathway, in independent samples. In the case of adipose cells or tissues, Adachi et al. (23) identified 3,287 proteins from mouse 3T3-L1 adipocytes, and Xie et al. (24) identified 1,493 proteins from abdominal SATs of three healthy individuals. These studies showed that these proteomes are involved in adipose functions that can thus serve as useful resources for various studies of adipose-related diseases. However, these proteomes were measured from adipose cells and SATs under nonpathogenic conditions. Comprehensive proteomes of VATs in T2DM patients and subjects with normal glucose tolerance (NGT), as well as comparative analysis of proteomes between subjects with T2DM and NGT, have not been systematically explored in terms of the molecular signatures related to the pathogenesis of T2DM.

Here, we have undertaken an extensive proteome profiling of VATs obtained from drug-naïve early T2DM patients (duration of diagnosis of diabetes within 5 years) and subjects with NGT. In this study, we analyzed whole VATs, including adipocytes and vessel and inflammatory cells, after carefully removing blood, to produce the data representing cross-talk among these cells during the development of T2DM-related alteration in VATs. A sample preparation method utilizing filter-aided sample preparation (25), with certain steps slightly modified to improve protein extraction. Briefly, 100 μl of protein lysate was added to the concentrate for alkylation for 25 min at 25 °C in the presence of 10 mM iodoacetamide in 8M urea in 0.1 M Tris-HCl (pH 7.6) and then boiled for 10 min to remove excessive protein solubilization and the subsequent separation of proteins from lipid (29, 30). The lysate was transferred to a new tube and centrifuged at 14,000g for 15 min at 4 °C, and the resulting floating mature adipocytes and the stromal vascular fraction cell pellet except the lipid portion on the top was carefully recovered (27, 28). Removal of the lipid layer was very important, as it interferes with protein solubilization and the subsequent separation of proteins from lipid (29, 30). The lysate was transferred to a new tube, and the protein concentration was determined using a BCA protein assay (Pierce, Rockford, IL) and bovine serum albumin (Pierce) as a standard protein for the assay. No depletion of abundant proteins was attempted.

**Enzymatic Digestion**—Peptide samples were prepared via filter-aided sample preparation (25), with certain steps slightly modified to improve protein extraction. Briefly, 100 μg of protein lysate was reduced in 100 μl of SDT (4% SDS and 0.1 mM DTT in 0.1 M Tris-HCl, pH 7.6) for 45 min at 37 °C and then boiled for 10 min to remove excess DTT and SDS. The lysate was centrifuged at 14,000g for 40 min at 4 °C, and the supernatant was used for the following step.

**Patient Enrollment and Sample Collection**—We collected two independent sets of whole VATs from T2DM and healthy subjects who underwent elective abdominal surgery in Seoul National University Bundang Hospital (SNUBH). The first set of five T2DM patients and six healthy subjects was used for the proteome profiling (supplemental Fig. S1). We enrolled T2DM patients who had been diagnosed with diabetes within the past 5 years based on American Diabetes Association criteria (26) and had undergone only lifestyle modification, without taking antidiabetic medication (drug naïve). They showed normal body mass index values (<25 kg/m²) and had no past history of major adverse cardiovascular events, acute inflammatory diseases, or cancer. We excluded drug-naïve subjects with uncontrolled diabetes showing hemoglobin A1c > 8%. The control group with NGT was enrolled based on the same American Diabetes Association criteria. They were also confirmed by means of a 75-g oral glucose tolerance test and were age and sex matched. To confirm the validity of the selected proteins by Western blotting, we assembled a second test set that comprised 10 T2DM patients and 10 individuals with NGT who had undergone elective cholecystectomy and thoracic surgery in SNUBH. Informed consent was obtained from all subjects. This study was conducted according to the Declaration of Helsinki and was approved by ethics committees of SNUBH (SNUBH IRB#B-1203/147–006, #A111218-CP02). The clinical characteristics of all enrolled patients for proteome profiling and for confirming candidate proteins are described in supplemental Table S1.

**Homogenization and Protein Extraction**—Fat samples from surgery were immediately sent to our laboratory, where they were washed three times in phosphate-buffered saline (PBS) solution to remove blood clots and stored in a −80 °C refrigerator. Surgeons intended to collect VATs from the same area when possible, and these samples were mostly omental fat from close to the transverse colon. Frozen VATs were slowly thawed in ice for the next step and then very carefully and gently washed in ice-cold PBS to remove excessive blood contamination. Fat tissues were minced with scissors into small pieces, collected in test tubes, transferred to FastPrep tubes containing mini beads, and homogenized in 0.1 m Tris-HCl (pH 7.6) by a FastPrep beater (Bio101Savant, Carlsbad, CA) until there were no tissue pieces. The lysate was transferred to a new tube and centrifuged at 14,000g for 15 min at 4 °C, and the rest (the floating mature adipocytes and the stromal vascular fraction cell pellet) except the lipid portion on the top was carefully recovered (27, 28). Removal of the lipid layer was very important, as it interferes with protein solubilization and the subsequent separation of proteins from lipid (29, 30). The lysate was transferred to a new tube, and the protein concentration was determined using a BCA protein assay (Pierce, Rockford, IL) and bovine serum albumin (Pierce) as a standard protein for the assay. No depletion of abundant proteins was attempted.

**Enzymatic Digestion**—Peptide samples were prepared via filter-aided sample preparation (25), with certain steps slightly modified to improve protein extraction. Briefly, 100 μg of protein lysate was reduced in 100 μl of SDT (4% SDS and 0.1 mM DTT in 0.1 M Tris-HCl, pH 7.6) for 45 min at 37 °C and then boiled for 10 min to remove excess DTT and SDS. The lysate was centrifuged at 14,000g for 40 min at 4 °C, and the supernatant was used for the following step.
overnight digestion without agitation. After the first digestion, a second trypsin digestion (1:100 enzyme-to-protein ratio) was carried out for 6 h. The digested peptides were eluted from the filter via centrifugation at 14,000g for 30 min, the filter was rinsed with 60 μl of 50 mM NH₄HCO₃ and centrifuged at 14,000g for 20 min, and the flow-through was mixed with the first eluent. The eluent was treated with 5 μl of formic acid, incubated for 45 min at 37 °C, and then centrifuged at 14,000g for 10 min to remove the RapiGest reagent. The supernatant was transferred to a new tube and dried completely using a SpeedVac concentrator (Thermo, San Jose, CA). Dried peptides were stored at −80 °C.

**Isoelectric Focusing of Peptides**—10 μg of each of 10 fat peptide samples (5 NGT and 5 T2DM) were collected and then pooled (total = 100 μg). The pooled sample was divided into 26 fractions using a 3100 OFFGEL Fractionator (Agilent Technologies, Santa Clara, CA) (32). Briefly, a 24-cm-long immobilized pH gradient gel strip (pH 3–10, GE Healthcare Life Sciences) was rehydrated for 15 min with the addition of 25 μl of rehydration solution to each well of a 24-well tray. The 100 μg of pooled peptides was dissolved in 0.72 ml of distilled water. The peptide solution was mixed with 2.88 ml of OFFGEL stock solution, and 150 μl of the total of 3.6 ml was loaded into each of 24 wells. The peptide sample was focused at 20 °C with a maximum current of 50 μA, and the voltage range was from 500 to 8,000 V until reaching 50 kVh. After the focusing, the peptides were recovered from the 24 wells. We also collected peptides from both the anode end (consisting of peptides having pI values less than 3) and the cathode end (consisting of peptides having pI values greater than 10). Thus, 26 fractions were prepared in total. Glycerol was removed by desalting in a spin column (Harvard Apparatus, Holliston, MA) before each of the fractionated peptides was vacuum-dried. Dried peptides were stored at −80 °C.

**LC-MS/MS Experiments**—A total of 59 LC-MS/MS datasets from normal, diabetes mellitus, and OFFGEL fractions of pooled samples were separated using a modified version of the nanoACQUITY UPLC (NanoA, Waters, Milford, MA) system (33). An analytical column (75 μm inner diameter × 360 μm outer diameter × 70 cm length) was manufactured in-house by acetonitrile slurry packing a fused-silica capillary (Polymicro Technologies, Phoenix, AZ) with C18 materials (3 μm diameter, 30 Å pore size; Jupiter, Phenomenex, Torrance, CA). The solid phase extraction column was prepared by packing the same C18 materials into the 1-cm-long inner (250 μm inner diameter) of an internal reducer (1/16 inch to 1/32 inch, VICI, Houston, TX). The column temperature was set at 50 °C using a semi-rigid gas heating (1/4-inch inner diameter, 60-cm length, WATLOW, St. Louis, MO.) (34). For 26 OFFGEL fraction samples, the LC separation gradient was 98% solvent A (0.1% formic acid in H₂O) for 5 min, 2% to 50% solvent B (0.1% formic acid in 99.9% acetonitrile) in 115 min, 50% to 80% solvent B in 10 min, and 80% solvent B in 10 min. For the triplicate LC-MS/MS experiments on the unfractonated individual samples, the LC gradient was 98% solvent A (0.1% formic acid in H₂O) for 5 min, 2% to 50% solvent B (0.1% formic acid in 99.9% acetonitrile) in 235 min, 50% to 80% solvent B in 10 min, and 80% solvent B in 10 min. The flow rate of the mobile phase was set at 400 nl/min. A 7-tesla Fourier transform ion cyclotron resonance mass spectrometer (LTQ-FT, Thermo Electron, San Jose, CA) was used to collect the mass spectra. The eluted peptides from the LC were ionized at an electrospray potential of 2.0 kV. The electrospray ionization emitter was manufactured by chemical etching of a fused-silica capillary emitter (20 μm inner diameter × 150 μm outer diameter) (35). The temperature of the desolvation capillary was set at 250 °C. MS precursor ion scans (m/z 500–2,000) were acquired in a full-profile mode with an automatic gain control target value of 1 × 10⁶, a mass resolution of 1 × 10⁵, and a maximum ion accumulation time of 500 ms. The mass spectrometer was operated in data-dependent tandem MS mode; the seven most abundant ions detected in a precursor MS scan were dynamically selected for MS/MS experiments incorporating a dynamic exclusion option (exclusion mass width low, 1.10 Th; exclusion mass width high, 2.10 Th; exclusion list size, 120; exclusion duration, 30 s) to prevent reacquisition of MS/MS spectra of the same peptides. Collision-induced dissociations of the precursor ions were performed in an ion trap (LTQ) with the collisional energy and isolation width set to 35% and 3 Th, respectively. The Xcalibur software package (v. 2.0 SR2, Thermo Electron) was used to construct the experimental methods.

**Database Search for Peptide Identification**—The integrated post-experiment monoisotopic mass refinement (iPE-MMR) method was used to process the LC-MS/MS data and was previously demonstrated to accurately assign precursor masses to tandem mass spectrometric data before a subsequent protein database search (36). Briefly, DeconMsn (37) was used to generate MS/MS data (DTA files) whose precursor masses were further corrected and refined through PE-MMR (38). The resultant mass-refined DTA files were subjected to multivariate mass error correction using DataRefinery (39, 40). The resultant MS/MS data after iPE-MMR processes were searched against a composite target-decoy database that contains human data (IPR v. 3.86, 91,550 entries) and its reversed complements using the SORCERER™-SEQUEST (v. 3.5) search algorithm (Sage-N Research, Milpitas, CA). The searches were performed allowing for semi-tryptic peptides, and the maximum allowable number of missed cleavages was 3. The mass tolerance was 10 ppm for precursor ions and 1 Da for fragment ions. The carbamidomethylation of cysteine (57.021460 Da) was used as a static modification. Variable modification options were used for the oxidation of methionine (15.994920 Da) and the carbamylation of N-terminal sites (43.005810 Da). The search results were filtered using an estimated false discovery rate (FDR). The FDR of peptide assignments was estimated through a composite target-decoy database search. The values of Xcorr and the ΔCn threshold for the 1% FDR were used to obtain peptide I.D.s (41).

**Assigning MS Intensity to Peptide Identification**—An MS intensity-based label-free quantitation method was applied to adipose tissue LC-MS/MS data (33 LC-MS/MS data) as described previously (41). Briefly, during PE-MMR analysis, MS features of a peptide that emerged over a period of LC elution time in an LC-MS/MS experiment were grouped into a unique mass class (UMC) (38). Each UMC contained all mass spectral features of a peptide, such as charge states, abundances (intensity), scan numbers, and measured monoisotopic masses. Ideally, a peptide is represented by a UMC. For each UMC, the UMC mass was calculated as the intensity-weighted average of the monoisotopic masses of all the UMC components, and the abundance summation of all mass spectral components of the UMC (UMC intensity) was calculated to represent the experimental peptide abundance. During PE-MMR analysis, the precursor masses of the MS/MS spectra (or DTA files) were searched for matches with UMC masses and were replaced by the UMC masses when a match was found. In this process, DTA information was linked to the matched UMC. When the linked DTA file resulted in a peptide sequence with a false positive rate of 1% after SEQUEST searching and target-decoy analysis, the peptide I.D. was recorded in the UMC and the UMC intensity was assigned to the peptide I.D. In this study, normalized elution time (NET) prediction was used to calculate the NETs of the identified UMCs in order to minimize the LC elution time variance of the same peptide across the different LC/MS runs (42).

**Construction and Utilization of VAT Master Accurate Mass and Time Tag Database**—Information about UMCs with peptide I.D.s from 59 LC-MS/MS data (triplicate LC-MS/MS experiments of 11 samples and 26 LC-MS/MS experiments of OFFGEL fractionates) was compiled into the master accurate mass and time tag (AMT) database (DB) (Oracle Database 10g Enterprise Edition, Release 10.2.0.1.0; Fig. 1A).
A Protein Profile of VATs Linked to Pathogenesis of T2DM

It is an assembly of AMTs, which are unique peptide sequences whose monoisotopic mass and NET are experimentally determined. When peptides were measured multiple times, the average mass and the median NET were recorded for each AMT.

Due to undersampling of the current proteomic analysis platform, a large portion of UMCs from an LC-MS/MS experiment was not identified in MS/MS experiments and protein database searches. For example, from an individual LC-MS/MS dataset, 87,937 UMCs were measured in MS spectra, and 4,618 of them (approximately 5.3%) were identified by protein database search (identified UMCs; Fig. 1B, right top). Peptide ions that were detected in MS scan but with no chance of MS/MS analysis or ions that had undergone fragmentation but with low quality are the main causes of such unidentified UMCs. To assign peptide I.D.s to unidentified UMCs, they were matched to the master AMT DB under mass and NET tolerances (i.e. ±10 ppm, ±0.025 NET each; Fig. 1B, right bottom). This process of assigning peptide I.D.s to unidentified UMCs resulted in 6,182 additional UMCs identified by the master AMT DB information, making the total number of UMCs with peptide I.D. assignments 10,800 (assigned UMCs).

Alignment of Identified Peptides—After the unidentified UMCs had been assigned with the information from the master AMT DB, the resultant assigned UMCs from the 33 LC-MS/MS datasets of 11 individual VAT peptide samples) were combined into an alignment table in which each row contained the peptide I.D.s with their corresponding UMC sum intensities from each LC-MS/MS experiment. Quantile normalization of the aligned data was performed to correct the variation in peptide abundance (43) due to variations in the injection amount, and median abundance values of triplicates were obtained. For evaluation of the data reproducibility, similarity scores of two LC-MS/MS datasets of 11 individual VAT peptide samples were measured based on the overlap of detected peptides and their intensity values, as previously described (supplemental Fig. S2) (44). Quantified peptides were rolled up to protein inference by means of bipartite graph analysis (45). The representative protein of each protein group after bipartite graph analysis was set as the protein with the maximum number of unique peptides mapped to a single protein. If two or more proteins in one group had the same number of unique peptides, then the protein with the higher sequence coverage was considered as the representative protein.

Identification of Differentially Expressed Proteins—The intensities of the 22,250 aligned peptides (supplemental Table S2) were normalized using the quantile normalization method (43). From peptide intensities, the relative abundances of corresponding proteins were computed using a linear-programming formulation as described by Dost et al. (46). From among the quantified proteins, we selected proteins with at least two nonredundant peptides detected. To identify differentially expressed proteins (DEPs), a log2 median ratio test was performed to compute the significance of log2 median ratios for all the proteins (47). An empirical distribution of the null hypothesis (i.e. that a protein is not differentially expressed) was estimated by performing hundreds of random permutations of samples and then applying the Gaussian kernel density estimation method to log2 median ratios resulting from the random permutations (48). FDRs were then computed using the Storey method (49). The DEPs were identified as the ones with an FDR ≤ 0.05 (absolute log2 fold-changes larger than 1.16, the mean of the 0.25th and 97.5th percentiles of the null distribution).

Enrichment Analysis of GO Biological Processes—Functional enrichment analysis of DEPs was performed using DAVID software (50). GO biological processes enriched by the DEPs were identified as those with p < 0.05. We used the p values provided in DAVID.

Reconstruction of Network Model—To reconstruct a network model for DEPs, we first selected a subset of DEPs belonging to GO biological process terms enriched by DEPs and collected their protein–protein interactions from MetaCore™ and four protein–protein interactome databases: BIND (Biomolecular Interaction Network Database) (51), HPRD (Human Protein Reference Database) (52), BioGRID (Biological General Repository for Interaction Datasets) (53), and MINT (Molecular INTeraction Database) (54). The initial network model was built with selected DEPs and their interactions using Cytoscape (55). To incorporate current knowledge into the network, we added proteins involved in immune and metabolic systems and known to contribute to the pathogenesis of metabolic diseases in adipose tissue to the initial network. We then arranged the nodes according to their associated GO biological processes and pathways so that the nodes with similar functions were closely located. A group of nodes involved in the same GO process was labeled with the corresponding GO term.

Western Blot Analysis—For protein confirmation by Western blot, human visceral fat tissue was homogenized in a lysis buffer (Cell Signaling #9803, Danvers, MA) supplemented with protease inhibitors (1 mm phenylmethylsulfonyl fluoride; 100 mm; 2 g/ml aprotinin, 2 g/ml leupeptin). Lipids were eliminated via centrifugation of the solubilized samples at 13,000 rpm for 30 min at 4 °C. The supernatant was collected, and the protein concentration was checked by Bradford assay at 595 nm. Cell lysates (50 μg) were subjected to 10% SDS-PAGE and transferred onto nitrocellulose membranes. The membranes were incubated with primary antibodies. After washing, the blots were incubated with HRP-conjugated secondary antibodies. The blots were then quantified with Fujifilm Multi Gauge version 3.0. The list of primary antibodies for the selected secretory proteins is summarized in supplemental Table S3.

RESULTS

Comprehensive Global Profiling of VAT Proteome—We first carefully selected drug-naive T2DM patients (n = 5) with diabetes of a short duration (<5 years) and age- and sex-matched subjects with NGT as a control group (see “Experimental Procedures”). Enrolled subjects in this study were all cancer free. The baseline characteristics of T2DM patients and subjects with NGT, such as age, gender, body mass index, disease duration, and other laboratory measures, are summarized in supplemental Table S1. We isolated VATs from elective abdominal surgery for the T2DM patients and normal controls. After removing blood clots, we obtained the lysates of the VATs, removed the lipid layer from the lysates, and then used the filter-aided sample preparation method (25, 56) for protein digestion (see “Experimental Procedures” for details).

To extensively profile the VAT proteome, we generated a master AMT DB (Fig. 1). To this end, we first pooled five normal and five T2DM samples, carried out off-gel fractionation of the pooled proteome into 26 fractions, and analyzed the fractions using ultra-high-pressure nano-LC-MS/MS (Fig. 1A). This resulted in 26 LC-MS/MS datasets (supplemental Fig. S3). In addition, we performed triplicate experiments on each of the VATs from five T2DM patients and six subjects with NGT, resulting in 33 LC-MS/MS datasets (supplemental Figs. S4 and S5). A total of 59 LC-MS/MS experiments were used to construct a master AMT DB of the VAT proteome. Briefly, we generated UMCs of peptide MS features from
The master AMT DB for the VAT proteome. A, the overall scheme of the AMT DB construction. A total of 59 datasets were generated from LC-MS/MS analysis. Each of the 59 datasets was processed by iPE-MMR, after which SEQUEST searching was performed. The target-decoy (TD) analysis was performed for the datasets, and then the resultant peptides (or unidentified UMCs) from both were used to construct the AMT DB (see “Experimental Procedures”). B, utilization of AMT DB to assign peptide I.D.s to unidentified UMCs. The 25,418 AMTs (magenta dots) in the AMT DB are visualized in a two-dimensional (NET and molecular weight) scatter plot (left). For an LC-MS/MS dataset, the identified UMCs (blue dots) are shown in the upper-right scatter plot. By matching unidentified UMCs in this dataset with AMTs (see “Experimental Procedures”), additional identification was obtained (4,618 Identified UMC). The comparison showed that 1,089 (73.8% of 1,476) and 1,330 (44.4% of 2,997) gene products were also detected in VATs (Fig. 2B). Among the 2,323 genes, 1,542 (66.4%) were detected in at least one of the two studies, and 781 were not detected. These data indicate that our VAT proteome can serve as one of the comprehensive proteomes of adipose tissues.

We then examined cellular processes represented by the 4,707 VAT proteins by performing enrichment analysis of Gene Ontology biological processes (GOBPs) using DAVID software (50). The cellular processes significantly represented by the VAT proteome include the processes related to major functions of adipose tissues, such as oxidation reduction, homeostatic process, inflammatory/immune response, and glucose and lipid metabolic processes (Fig. 2C; supplemental Table S5A). The enrichment analysis of GO cellular components also revealed that a majority of the VAT proteins were mainly localized in the (i) plasma membrane (21.1%), (ii) cytosol (20.1%), (iii) mitochondrion (15.8%), (iv) extracellular region (14.6%), (v) cytoskeleton (11.2%), (vi) endoplasmic reticulum (8.0%), (vii) vesicle (7.8%), and (viii) Golgi apparatus (5.7%) (Fig. 2D; supplemental Table S5B). These data indicate that our VAT proteome can provide information related to...

**Fig. 2. Comprehensive proteome of VATs measured from 59 LC-MS/MS analyses.**

A. Comparison of VAT proteome with proteomes previously measured from adipose tissues or cells. The numbers of proteins and genes encoding detected proteins in each study are shown. B. Venn diagram showing the relationships of VAT proteome with the adipose proteomes previously reported based on the genes encoding detected proteins in each study. C. Cellular processes (GOBPs) in which the identified VAT proteins are mainly involved. The bars represent -log10(P), where P represents the significance of each GOBP being enriched by the VAT proteins. The p value was computed by the DAVID software. D. Relative proportions of Gene Ontology cellular components in which the measured VAT proteins are mainly localized.

Diverse functions of adipose tissues occurring in various cellular compartments.

**Identification of VAT Proteins Altered in T2DM**—To identify VAT proteins whose abundances were altered in T2DM relative to NGT, we first aligned each of 22,250 peptides in the 33 LC-MS/MS datasets (15 for five T2DM patients and 18 for six subjects with NGT) and then determined the ratios of abundances of the 4,707 VAT proteins between T2DM and NGT samples using the linear programming method previously reported (46) (see “Experimental Procedures” for details). Based on the protein ratios, we then identified 772 DEPs (FDR < 0.05) between the VATs of subjects with NGT and T2DM (“Experimental Procedures”; supplemental Table S6). Of the 772 DEPs, 444 proteins increased in abundance in T2DM relative to NGT, whereas 328 decreased in T2DM.

To understand the functional association of the DEPs with T2DM, we identified cellular processes represented by the 772 DEPs using DAVID software. This analysis revealed that 444 up-regulated DEPs were mainly involved in inflammatory/immune responses, cytoskeleton organization–related processes (cell migration and cell adhesion), and responses to reactive oxygen species and oxidative stress (Fig. 3A; supplemental Table S7A), consistent with previous findings recognizing inflammation responses and oxidative stress as major causes of T2DM pathogenesis (1, 57, 58). The 328 down-regulated DEPs were mainly involved in glucose and fatty acid metabolic processes that contribute to T2DM pathogenesis (Fig. 3B; supplemental Table S7B). A number of studies have demonstrated that the inflammation/immune system and metabolism are highly integrated (58, 59), indicating that the up- and down-regulated DEPs collectively act to define T2DM-related pathophysiology in VATs.

To explore the collective function of these T2DM-related processes, we reconstructed network models describing the interactions among the DEPs involved in the processes represented by the 444 up-regulated DEPs (Fig. 3C) and the 328 down-regulated DEPs (Fig. 3D). The DEPs in these network models were grouped into functional modules, each of which included the DEPs involved in the corresponding GOBP shown in Figs. 3A and 3B. Several modules, including complement cascade, inflammatory/immune response, and ECM-receptor interaction, showed dense interactions within themselves and between one another through transcription factors (NFKB1/RELA, STAT3, and STAT5B) (Fig. 3C). Also, significant numbers of molecules involved in metabolic pathways (pyruvate metabolism, tricarboxylic acid cycle, OXPHOS, and fatty acid β-oxidation) were decreased in T2DM (Fig. 3D).
These data indicate a collective contribution of these modules and pathways to T2DM pathogenesis.

A Proteome Profile Representing the Pathophysiology of VAT—VATs in T2DM are characterized by chronic inflammation and metabolic alterations (57–59). Consistently, the network models showed alterations of the processes related to inflammation (Fig. 3C) and metabolism (Fig. 3D) in T2DM VATs. Thus, to select a proteome profile that could represent the collective pathophysiology of VATs in T2DM, we focused on 21 secretory DEPs involved in the three inflammation-related modules of inflammatory/immune response, complement cascade, and cell adhesion in the network model (Fig. 3C; supplemental Fig. S7). From among these, we selected the following five proteins that can represent the alterations of the processes corresponding to the network modules: \( \alpha \)-2-HS-glycoprotein and S100 calcium binding protein A8/9 (S100A8/9; Calprotectin) for the inflammatory/immune response module; complement component 1, q subcomponent, A chain (C1QA) for the complement cascade module; and sorbin and SH3 domain containing 1 (SORBS1) for the cell adhesion module. Second, for the metabolism-related processes in the network model, we focused on seven DEPs involved in the pathway of fatty acid \( \beta \)-oxidation, which is...
A Protein Profile of VATs Linked to Pathogenesis of T2DM

more relevant to adipose tissue than the glycolytic pathway, in the network model (Fig. 3D). From among them, we selected three metabolic enzymes, carnitine palmitoyltransferase 2, acyl-CoA dehydrogenase, long chain (ACADL), and acyl-CoA dehydrogenase, C-4 to C-12 straight chain (ACADM) (supplemental Fig. S8). Third, adipokines are the most well-known class of proteins secreted from adipose tissue, which can affect both inflammation and metabolic alterations in T2DM VATs. Interestingly, the 320 secretory DEPs included the three adipokines fatty acid binding protein 4 (FABP4) and perilipin 1 and 4 (PLIN1 and PLIN4). Thus, we selected additionally these three adipokines. A total of 11 proteins were selected as a protein profile that could represent the pathophysiology of VAT in the early pathogenesis of T2DM.

Validation of the Selected Protein Profile—To test the validity of the 11 selected proteins, we collected the VATs from an independent set of 10 early T2DM patients and 10 subjects with NGT based on the same criteria (“Experimental Procedures”) employed for the collection of the samples at the discovery phase using LC-MS/MS analysis (supplemental Table S1). In these new samples, using Western blotting, we then tested the differential expression of the 11 selected proteins measured by LC-MS/MS analysis (i.e. up-regulation of FABP4, S100A8/9, SORBS1, α-2-HS-glycoprotein, and C1QA and down-regulation of PLIN1/4, carnitine palmitoyltransferase 2, ACADL, and ACADM in T2DM relative to NGT; 11 proteins in red in supplemental Fig. S7). From among the 11 selected proteins, we finally selected the six proteins that showed significant changes in the independent samples consistent with those shown in the LC-MS/MS data (Figs. 4A and 4B, supplemental Fig. S8). Finally, we assessed whether the six proteins could be used to monitor the pathophysiology of VATs in T2DM. To this end, we quantified the abundances of the six proteins from the results of Western blotting and then evaluated whether their abundances were capable of distinguishing T2DM patients from subjects with NGT using partial least square discriminant analysis (Fig. 4C) (41). Nine out of the 10 T2DM samples were correctly separated from the 10 NGT controls. Taken together, these data indicate that the six proteins can be used as a protein profile that represents the pathophysiology of VAT in the early pathogenesis of T2DM.

DISCUSSION

Visceral fat accumulation is a key feature of chronic metabolic diseases related to lipotoxicity, such as diabetes, metabolic syndrome, obesity, and cardiovascular disease. Metabolic and functional disruption in adipose tissue can serve as an essential dimension of molecular signatures that can be used to understand the pathogenesis of T2DM. However, the alteration of these signatures in VATs has been considered clinically important but has not been systematically explored. In this study, we thus examined comprehensive proteome profiles of VATs to identify a proteome profile representing key pathophysiological features of VATs, inflammation of adipose tissue and metabolic alteration, linked to the pathogenesis of T2DM. To achieve this goal, we developed an approach that involved (i) comprehensive proteome profiling of whole VATs with removal of blood clots and lipid layers from the lysates, generation of a master AMT DB, and ultra-high-pressure nano-LC-MS/MS analysis; (ii) identification of DEPs in the VATs collected from subjects with T2DM and NGT; (iii) the selection of a protein profile able to represent the T2DM-
related pathophysiology of VATs by integrating T2DM-related network models of VATs and functions of the proteome secreted from VATs; and (iv) validation of the selected protein profile in independent T2DM using Western blotting and confirmation of the validated protein profile able to distinguish T2DM samples from NGT controls by means of partial least square discriminant analysis. Using this approach, we identified a protein profile composed of six VAT proteins (three up-regulated and inflammation-related (S100A8, C1QA, and SORBS1), one down-regulated and metabolism-related (ACADL), and two adipokines (FABP4 and PLIN4)).

A number of previous studies have shown associations of the six proteins selected in this study with T2DM in various systems (e.g., serum/plasma, urine, muscle, or liver; supplemental Table S9). A higher serum FABP4 level was linked to obesity, insulin resistance, and T2DM (62, 63). The amount of the serum C1q-adiponectin complex showed a significant correlation with coronary artery disease in Japanese T2DM subjects (64). The amounts of S100A8/9 (calprotectin) in both urine and plasma were associated with chronic low-grade inflammation and insulin resistance (65, 66), and mRNA levels of S100A8 were elevated in the adipocyte fraction of obese mice (67). SORBS1(CAP) blocks the stimulation of glucose transport by insulin in 3T3-L1 adipocytes (68), and the T228A polymorphism of SORBS1 was linked to both obesity and diabetes (69). ACADL knockout mice showed increased triglyceride storage in both muscle and liver and severe hepatic insulin resistance (70). The 11482G→A polymorphism of the PLIN4 gene was associated with a higher risk of obesity and metabolic syndrome (71). However, none of these proteins have been previously reported to be altered in their protein levels in human adipose tissue or VATs of early T2DM relative to normal controls (supplemental Table S9). Note that the mRNA levels of S100A8/9 were elevated in the mouse adipocyte fraction. These data indicate two aspects of the six-protein panel: (i) the alterations of mRNA or protein levels of these proteins in other systems suggest the validity of the six proteins as a protein profile that can represent the pathophysiology of T2DM VATs; and (ii) the fact that no alterations of these proteins in protein levels were previously shown in human adipose tissue or VAT suggests the novelty of the six-protein panel.

Previously, Xie et al. and Adachi et al. provided the proteomes of abdominal SATs of healthy individuals and mouse 3T3-L1 adipocytes, respectively (supplemental Table S9). Although these datasets could have served as useful resources for various studies of adipose-related diseases, neither study compared the proteomes with those in T2DM, and thus they provide no lists of DEPs in T2DM relative to normal controls. Four of the six proteins were detected in either of these studies, but alterations of their abundances in T2DM have remained unknown. Also, several studies (18, 19, 72, 73) have included comparative proteomic analyses in muscle, salivary, serum, and pancreatic islet tissues, providing the proteomes and lists of DEPs in these tissues collected from T2DM patients or mice relative to controls (supplemental Table S9). Among the six proteins, three (S100A8, C1QA, and FABP4) have been detected in one of these tissues, but only C1QA showed alteration in its protein abundance in T2DM serum. Nonetheless, none of the six proteins selected in this study have been previously reported to be altered in protein levels in human adipose tissue or VATs in early T2DM.

Taken as a whole, our study showed for the first time the differential expression of six selected proteins that have been previously linked to T2DM pathogenesis in other systems in VATs of early T2DM patients, thereby supporting their potential use as indicators of the early pathogenesis of T2DM. The clinical implications of the six selected proteins can be further tested with a larger number of early T2DM patients. In addition, longitudinal studies can be designed to further demonstrate the nature of dynamic changes of the proposed protein profile during the course of T2DM pathogenesis. Also, novel subtypes of early, drug-naïve T2DM patients might be further characterized based on the dimension of inflammation of adipose tissue and metabolic changes in VATs represented by the proposed protein profile.

The six selected VAT proteins correctly distinguished 90% of T2DM patients from subjects with NGT, suggesting the potential use of the selected proteome profile in understanding the pathophysiological states of T2DM (Fig. 4C). One T2DM sample was classified into NGTs. We carefully examined clinical characteristics of this patient and compared them with those of the other T2DM patients. Disease duration, diabetes mellitus status, and management of this outlier patient were similar to those of the other T2DM patients. However, this patient was the oldest man in our test set and had taken antihypertensive medication for more than 4 years. The patient’s age of 75 (mean age = 66.8 in the test set) survivor deviation, and the history of hypertension could have induced the difference between this patient and the other T2DM patients, and/or the antihypertensive medication could have made the profile of the six selected DEPs in this patient similar to those in NGTs. However, more detailed functional studies should be carried out to elucidate the mechanisms underlying the similarity in the profiles of the six selected DEPs between this patient and NGTs.

In addition to the six proteins selected in this study, our approach provided a comprehensive list of DEPs or secretory proteins in VATs in early T2DM pathogenesis, thus extending extensively the current list identified by conventional small-scale experiments or approaches (supplemental Table S6). This list of proteins can serve as a comprehensive resource for biologists who study adipose tissue and interactions among the cells constituting VATs based on the DEPs and secretory proteins, respectively. Furthermore, the network models can provide a basis for understanding inflammation of adipose tissue (Fig. 3C) and metabolic alterations in VATs during the early pathogenesis of T2DM (Fig. 3D). The network
models further suggested that fatty acid oxidation, insulin signaling, adipose tissue inflammation, and PPARγ pathways associated with the DEPs should be involved in early pathophysiological changes of VATs in T2DM. This understanding can further suggest proactive therapeutic options involving antidiabetic treatments during the early pathogenesis of T2DM. In summary, our approach successfully identified a protein profile that can provide a novel dimension of information indicative of T2DM for the classification, therapy, and pathogenesis of T2DM.
