B Cell Fcγ Receptor IIb Modulates Atherosclerosis in Male and Female Mice by Controlling Adaptive Germinal Center and Innate B-1-Cell Responses

Jayashree Bagchi-Chakraborty, Anna Francis, Toni Bray, Leanne Masters, Dimitrios Tsiantoulas, Meritxell Nus, James Harrison, Michelle Broekhuizen, Jennifer Leggat, Menna R. Clatworthy, Marion Espéli, Kenneth G.C. Smith, Christoph J. Binder, Ziad Mallat, Andrew P. Sage

Objective—Investigate the impact of modulating B cell FcγRIIb (Fcγ receptor IIb) expression on atherosclerosis.

Approach and Results—Western diet–induced atherosclerosis was assessed in Ldlr+/− or Apoe+/− mice with B cell–specific overexpression of FcγRIIb or with an FcγRIIb promoter mutation that alters FcγRIIb expression in germinal center (GC) B cells. In males, overexpression of FcγRIIb on B cells severely reduced activated, class switched B cell responses, as indicated by reductions in GC B cells, plasma cells, and serum IgG but not IgM antibodies. Male mice overexpressing FcγRIIb developed less atherosclerosis, suggesting a pathogenic role for GC B cell IgG responses. In support of this hypothesis, male mice with a promoter polymorphism–driven reduction in FcγRIIb on GC B cells but not plasma cells have a converse phenotype of enhanced GC responses and IgG2c antibodies and enhanced atherosclerosis. IgG2c significantly enhanced TNF (tumor necrosis factor) secretion by CD11b+ CD11c+ cells expressing the high-affinity receptor FcγRI.

In females, overexpression of FcγRIIb on B cells not only reduced GC B cell responses but also substantially reduced B-1 cells and IgM antibodies, which translated into acceleration of atherosclerosis. Promoter–driven reduction in FcγRIIb did not alter GC B cell responses in females and, therefore, had no impact on atherosclerosis.

Conclusions—B cell FcγRIIb differentially alters proatherogenic adaptive GC B cell and atheroprotective innate B-1 responses in male and female mice fed a western diet. Our results highlight the importance of a better understanding and ability to selectively target B cell responses in future immunotherapeutic approaches against human cardiovascular disease.

Key Words: atherosclerosis ▬ cardiovascular diseases ▬ germinal center ▬ inflammation ▬ plasma cells

Despite significant progress in reducing mortality rates, the incidence and morbidity associated with cardiovascular disease, most commonly caused by underlying atherosclerosis, continues to represent a leading global health concern. Atherosclerosis is driven by an aberrant response to LDL (low-density lipoprotein) accumulation by both vascular wall cells and invading immune cells. The modification of LDL is hypothesized to drive these nonresolving inflammatory cycles. B cell responses have long been associated with atherosclerosis, particularly antibody responses to oxidized LDL. IgM antibodies to proinflammatory oxidation-specific epitopes are produced by innate-like B-1 cells, which exhibit atheroprotective properties. In contrast, autoantibody-driven autoimmune diseases, such as SLE (systemic lupus erythematosus), are associated with accelerated atherosclerosis progression, although the mechanisms linking the 2 diseases are still under investigation. Autoimmunity is associated with a break-in tolerance, that is, a failure of checkpoints during B cell or T cell activation and production of class-switched IgG, IgE, or IgA antibodies to autoantigens. B cell depletion therapy using anti-CD20 antibodies is effective against some autoimmune diseases and also mitigates cardiovascular disease in experimental models of atherosclerosis, myocardial infarction, abdominal aortic aneurysm, and hypertension.

See accompanying editorial on page 1269
A major effector mechanism of IgG antibodies is binding FcγRs (Fcγ receptors) on the cell surface of immune cells, distinguishing IgG functions from other isotypes such as IgM. There are several activating receptors (FcγRI, III, and IV in mice) expressed on monocytes, macrophages, dendritic cells, and neutrophils, which promote proinflammatory functions via immunoreceptor tyrosine-based activation motif-mediated signaling pathways. In contrast, there is a single inhibitory receptor, FcγRIIB, which antagonizes activating FcγR signaling through its intracellular immunoreceptor tyrosine-based inhibitory motif domains. FcγRIIB is also expressed on B cells, where it regulates B cell responses at multiple points. In fact, in humans, the major subtype expressing FcγRIIB is B cells. Co-ligation of the B cell receptor and FcγRIIB by antigen-IgG immune complexes raises the activation threshold compared with soluble antigen, limiting B cell responses. On antigen-IgG immune complexes raising the activation threshold.

Plaque and Serum Analysis
To assess plaque size and composition, aortic root cryosections were stained with Oil red O, hematoxylin and eosin, picrosiris red (All Sigma) or with anti–α-smooth muscle actin (Sigma), anti-CD3 (Dako) or MOMA2 (Bioread) antibodies. Images were analyzed using ImageJ (National Institutes of Health). Cellularity was determined by quantifying the proportion of nuclear-stained area within plaques (Hoechst staining). Serum total and oxidation-specific epitope antibodies were analyzed using kits from Bethyl labs or as previously described. Total cholesterol was quantified using a cholesterol RTU kit (Biomerieux) and serum BAFF by ELISA (BioTechne).

Immune Cell Phenotyping
Flow cytometry of single cell suspensions was performed as previously described. Flow cytometry antibodies are detailed in Table I in the online-only Data Supplement, and gating strategies are outlined in Figure I in the online-only Data Supplement. In some experiments, B-1 cells were alternatively gated as B220+ IgM+ CD5+ and germlinal center (GC) B cells as B220+ IgM+ CD95+ GL-7. In vitro, B cell proliferation was assayed using splenic B cells purified by negative selection (Milteny) after stimulation for 72 hours with anti-IgM whole IgG or Fab’ fragments (Southern Biotech). B-1 cells were enriched by fluorescence-activated cell sorting from peritoneum as B220+ IgM+ CD43+ CD23− cells. Apoptosis was assessed using an annexin V kit (Biomerieux) and serum BAFF by ELISA (BioTechne).

Methods
The data that support the findings of this study are available from the corresponding author on reasonable request.

Mice
Ldb−/− (002207) and Apeo−/− (002052) mice were originally obtained from the Jackson laboratory. FcγRIIB-B cell transgenic (Bγ) mice and FcγRIIB−/− mice were previously described. Both strains (created using C57BL6 embryos) were crossed to Apeo−/− mice. Bγ mice were maintained via transgenic/nontransgenic breeding. Control (FcγRIIB−/−; wild-type [WT]) mice were nontransgenic Apeo−/− littermates. Heterozygous FcγRIIB−/−AP-1 (+/+AP-1) mice were used as breeders, and data from control (BL6; +/+ or +/+AP-1) and homozygous mutant (ΔAP-1/ΔAP-1) littermates are presented. BM transfer experiments were performed as previously described. Mice received western diet (21% fat and 0.15% cholesterol; Scientific Diet Services) for 6 or 12 weeks. Mice from different experimental groups were co-housed for atherosclerosis experiments. For IgM half-life experiments, male and female Apeo−/− mice were injected intravenously with 200 μL of sex-matched Balb/c mouse serum (with normalized IgM concentration). Blood samples were collected 4, 25, and 48 hours post-injection from the saphenous vein. Mice were kept under a 12/12 hour light/dark cycle with access to food (DS150; SAFE) and water ad libitum. Cage bedding was from Datesand. All experiments were conducted under license and within the institutional guidelines of the University of Cambridge and adhered to the recommendations set out by the American Heart Association.
Results

B Cell Overexpression of FcγRIIb in Male Mice Reduces Atherosclerosis

Overexpression of FcγRIIb on B cells, mimicking the endogenous upregulation that occurs during B cell activation, was shown to protect mice in models of arthritis and SLE. We, therefore, designed experiments to examine the effect of B cell FcγRIIb overexpression on atherosclerosis using this previously described FcγRIIb-Btg mouse. The transgene results in specifically elevated FcγRIIb on B cells but not myeloid (CD11b+) cells (Figure 1A). We confirmed the functional impact of this by measuring the response to B cell activation in vitro with anti–B cell receptor (anti-IgM) antibodies with or without the FcγRIIb-recruiting Fc portion. The proliferation in response to anti-IgM IgG antibodies was severely attenuated in B cells from Btg Apoe−/− mice. When anti-IgM Fab' fragments (lacking Fc receptor-binding capacity) were used, there was a much smaller difference between WT and Btg B cells (Figure 1B), with the residual difference potentially caused by enhanced levels of apoptosis in Btg B cells. Indeed, in vivo, Btg mice have lower proportions of follicular B cells but similar proportions of other B-2 cell subsets (Figure 1C) and express elevated levels of proapoptotic Fas (Figure IIA in the online-only Data Supplement).

We first analyzed the impact on atherosclerosis using BM transplant from Btg or nontransgenic littermate control mice into irradiated Ldlr−/− mice. Atherosclerotic plaque size was reduced in Ldlr−/−/Btg mice compared with Ldlr−/−/WT mice (Figure 1D). Total cholesterol, body weights, and circulating monocyte numbers were not different between groups (Figure IIB through IID in the online-only Data Supplement). Using the same Ldlr−/− chimeric model, we did not observe any impact on atherosclerosis using mice with FcγRIIb overexpression driven by the macrophage-specific CD68 promoter (Figure IIE through IIF in the online-only Data Supplement), suggesting a more influential role for FcγRIIb-mediated control of B cells on atherosclerosis. Based on these results, we created Btg Apoe−/− mice and analyzed the impact of western diet–induced atherosclerosis in male mice. Atherosclerosis in the aortic root was similar after 6 weeks but significantly reduced in Btg Apoe−/− mice after 12 weeks of western diet (Figure 1E; Figure IIIA in the online-only Data Supplement). Again, there were no significant differences in total cholesterol, body weights, or circulating monocytes.

Figure 1. B cell overexpression of FcγRIIb (Fcγ receptor IIb) inhibits B cell activation and reduces atherosclerosis in males. A, Mean fluorescence intensity (MFI) for anti-FcγRIIb staining on B cells (B220+ IgM+) or CD11b+ cells from Apoe−/− or Btg Apoe−/− mice. B, Proliferation of purified B cells from Apoe−/− or Btg Apoe−/− mice after 72 h stimulation with anti-IgM whole IgG or Fab' fragments. C, Levels of spleen B cell subsets (see Methods and Figure I in the online-only Data Supplement) in Apoe−/− or Btg Apoe−/− mice. D and E, Atherosclerosis quantified using Oil Red O–stained aortic root cryosections from male Ldlr−/− mice transplanted with WT or Btg bone marrow and fed western diet for 6 wk (D; n=12/group) or Apoe−/− or Btg Apoe−/− mice after 6 or 12 wk western diet (E; n=8–12 per group). Scale bar=100 μm. *P<0.05. αBCR indicates anti-B cell receptor; Btg, B cell transgenic; CPM, counts per minute; FO, follicular; MZ, marginal zone 1; T1, transitional stage 1; T2, transitional stage 2; and WT, wild-type.
between groups (Figure IIIB through IIID in the online-only Data Supplement). There were no significant differences in spleen and BM cellularity between control and Btg mice (Figure IIIE and IIIF in the online-only Data Supplement). Further analysis of the atherosclerotic plaques revealed that there were no significant differences in key plaque components such as macrophages, smooth muscle cells, necrotic core, or collagen (Figure IIIG through IIJ in the online-only Data Supplement).

B Cell Overexpression of FcγRIIb Reduces GC-Dependent Antibody Responses

B cells regulate atherosclerosis via multiple mechanisms (reviewed in Sage et al2), including regulation of T cells,6,7,22,24,30 via the cytokine BAFF31 or via antibody responses.27,32,33 We, therefore, analyzed whether any of these mechanisms could explain the impacts on atherosclerosis in the Btg models. Previously, B cell depletion strategies led to reduced CD3+ staining in plaques and reduced T cell activation.6,24 Here, plaque CD3+ T cell levels were diminished in Ldlr−/−/Btg mice but not in Btg Apoe−/− mice (Figure IV A and IVB in the online-only Data Supplement), despite a significant reduction in activated effector memory T cells (Tem) in the spleen of both Ldlr−/−/Btg and Btg Apoe−/− mice compared with their respective controls (Figure IVC and IVD in the online-only Data Supplement). We recently found an important protective role for BAFF in atherosclerosis, which we suggest acted via macrophage-expressed TACI (transmembrane activator and CAML interactor)31; this provides an alternative mechanism for the protective effect of B cell depletion, which results in high BAFF levels.30 In Btg mice, BAFF levels were lower than in control mice (Figure IVE in the online-only Data Supplement). We then turned to the humoral response. A major phenotype of these mice is decreased plasma cell survival,13 which prompted us to analyze the humoral responses thought to play a role in atherosclerosis.2 Proportions of BM plasma cells were significantly reduced in Btg Apoe−/− mice compared with control littermates (Figure 2A). In agreement with this, total IgG levels in serum were decreased in Btg Apoe−/− mice (Figure 2B) and Ldlr−/−/Btg mice (Figure 2C) compared with respective controls, whereas total IgM levels were not affected (Figure 2D; Figure IVG in the online-only Data Supplement). FcγRIIb also directly inhibits GC B cells (by inhibiting BCR [B cell receptor] signaling26), which produce the class-switched antibody response and B-1 cells (by promoting apoptosis14), which

![Figure 2](image-url)
mainly produce IgM. In accordance with the antibody data, GC B cells were reduced in B<sup>tg</sup> Apoe<sup>−/−</sup> mice compared with Apoe<sup>−/−</sup> controls, whereas proportions of B-1 cells were not different (Figure 2D through 2E). The specific isotypes IgG1 and IgG2c are largely GC-dependent and known to be increased in atherosclerotic mice. The levels of both IgG1 and IgG2c were reduced in B<sup>tg</sup> Apoe<sup>−/−</sup> mice (Figure 2F and 2G). We also found similar reductions in MDA (malondialdehyde)-LDL-binding IgG1 and IgG2c (Figure 2H). In contrast, there were no differences in levels of IgM with specificities associated with B-1 cells, including MDA-LDL, antiphosphorylcholine, or the specific antiphosphorylcholine T15 clonotypic antibodies (Figure 2I). We also detected the same reductions in total and MDA-LDL IgG2c in Ldlr<sup>−/−</sup>/B<sup>tg</sup> mouse serums, without alteration of IgG1 and IgM levels (Figure IVH through IVJ in the online-only Data Supplement). We concluded that B cell FcγRIIb–driven reduction in atherosclerosis was associated with reductions in systemic CD4<sup>+</sup> T cell responses and IgG2c class-switched antibody responses.

Selective Decrease of FcγRIIb in GC B Cells Increases Atherosclerosis

The decrease in class-switched antibodies in B<sup>tg</sup> mice could be because of FcγRIIb acting directly on GC B cells, on which it inhibits activation, and on plasma cells, on which it promotes apoptosis. We, therefore, sought out a way to separate the impact of FcγRIIb on GC B cells from its role on plasma cells. Inbred mouse strains as well as wild-type strains from around the world display distinct haplotypes at the FcγRIIb locus. The haplotype carried by New Zealand black mice lacks an AP-1 (activating protein-1)-binding site in the proximal promoter region and was reported to lead to defective upregulation of FcγRIIb specifically upon GC B cell recruitment. By knocking in the New Zealand black haplotype FcγRIIb promoter sequence into the C57BL/6 mouse genome, FcγRIIb<sup>ΔAP-1</sup> mice display decreased FcγRIIb expression on GC B cells and consequently enhanced GC formation. Importantly, for our studies, FcγRIIb<sup>ΔAP-1</sup> mice have a mild autoimmune phenotype with no overt clinical signs up to 14

Figure 3. Decreased FcγRIIb (Fcγ receptor IIb) expression on germinal center (GC) B cells in FcγRIIb<sup>ΔAP-1</sup> male mice enhances GC responses and increases atherosclerosis. A, Mean fluorescence intensity (MFI) of anti-FcγRIIb staining on B cells subsets (Figure 1 in the online-only Data Supplement) in Apoe<sup>−/−</sup> or FcγRIIb<sup>ΔAP-1</sup>/Apoe<sup>−/−</sup> mice. B, Spleen GC B cell levels. C and D, Total serum IgG2c and IgG1. E, Atherosclerosis quantified using Oil Red O–stained aortic root cryosections from male Apoe<sup>−/−</sup> or FcγRIIb<sup>ΔAP-1</sup>/Apoe<sup>−/−</sup> mice after 6-wk western diet. N=6 to 8 per group. Scale bar=100 µm. F–H, Atherosclerotic plaque composition was analyzed for proportions of cells (F) or MOMA2<sup>+</sup>–stained area (G). A single outlier was excluded from the WT group in F. *P<0.05. AP1 indicates activating protein-1; BM, bone marrow; FO, follicular; MZ, marginal zone; Sp, spleen; T1, transitional stage 1; and T2, transitional stage 2.
months, with glomerular IgG deposition but no decrease in kidney function evident at that age.26 We crossed FcγRIIbΔAP-1 mice to the Apoe−/− background and confirmed comparatively reduced FcγRIIb levels on GC B cells in FcγRIIbΔAP-1 compared with control (FcγRIIbBL6) littermates (Figure 3A). Some reduction was also detectable in transitional cells entering the spleen and on naïve follicular cells; however, no difference was detected in marginal zone, B-1, or plasma cells, which all have higher expression levels than naïve B cells (Figure 3A), suggesting that the AP-1-binding site is not critical for upregulation in those cells. Indeed, the B cell compartment was grossly normal in FcγRIIbΔAP-1 compared with WT controls, with no differences in proportions of different B cell subsets (Figure VA in the online-only Data Supplement). Atherosclerosis-prone FcγRIIbΔAP-1 mice displayed a significant enhancement of GC B cells, follicular helper T cells (that participate in the GC reaction), and circulating IgG2c antibodies compared with FcγRIIbBL6 littermates (Figure 3B and 3C; Figure VB in the online-only Data Supplement). Serum IgG1 levels were not different (Figure 3D). In support of a proatherogenic role of enhanced GC responses, FcγRIIbΔAP-1 mice had bigger atherosclerotic plaques compared with FcγRIIbBL6 littermates (Figure 3E). This was not associated with changes in plasma cholesterol, body weight, or circulating monocytes (Figure VC through VE in the online-only Data Supplement). Atherosclerotic plaques were more cellular and contained more macrophages (Figure 3F and 3G), whereas CD3+ T cell proportions were similar to control mice (Figure VF in the online-only Data Supplement). Taken together, GC-B cell intrinsic FcγRIIb levels control a proatherogenic response.

Figure 4. IgG2c induces TNF (tumor necrosis factor) production by FcγRIIV-expressing CD11b+CD11c+ cells. A, Histograms of anti-FcgRIV staining on mouse blood myeloid cell subsets. B and C, Apoe−/− (B) or Ldlr−/− (C) mouse aortas were analyzed by flow cytometry for FcγRIV mean fluorescent intensity (MFI) in myeloid cell subsets based on CD11b, CD11c, and MHCI expression. D, GM-CSF (granulocyte-macrophage colony stimulating factor)-induced CD11c+CD11b+MHCIi cells were incubated with IFNγ (interferon-γ) for 24 h and then analyzed by flow cytometry for FcγRI, FcγRIIb/III, and FcγRIV. E, TNF production by GM-CSF–induced CD11c+CD11b+MHCIi cells after culture for 48 h±IFNγ on uncoated, mouse IgG2c, or mouse IgG1-coated plates. Relative levels in 4 independent experiments. F, TNF production by IFNγ-pretreated GM-CSF–induced CD11c+CD11b+MHCIi cells after culture for 48 h with uncoated, mouse IgG2c-coated, or mouse IgG1-coated beads. Relative levels in 2 independent experiments. *P<0.05, **P<0.01, ***P<0.005. GM-CSF indicates granulocyte-macrophage colony stimulating factor; MHCIi, major histocompatibility complex II; LPS, lipopolysaccharide; and SSC, side scatter.
IgG2c Induces TNF in FcγRIV-Expressing CD11c+ CD11b+ Cells

To understand the potential for IgG2c to directly regulate atherosclerosis, we analyzed the expression of its proinflammatory receptor FcγRIIb. FcγRIIb was most highly expressed on Ly6Clo monocytes in the blood, consistent with previous reports (Figure 4A). In the atherosclerotic mouse aorta, CD45+ CD11b+ CD11c+ cells (monocyte-derived macrophages/dendritic cells) expressed high levels of FcγRIIb (Figure 4B and 4C). To investigate the response of these cells to IgG2c in vitro, we cultured CD11b+ CD11c+ MHCII+ cells using BM monocytes differentiated with GM-CSF (moDCs). moDCs upregulated FcγRIIb in response to IFNγ, a known proatherosclerotic cytokine (Figure 4D). We then investigated the effect of mouse IgG2c and IgG1 antibodies as immune complexes on moDC activation, measured by TNF secretion, in 2 ways. First, we precoated culture plates with either IgG2c or IgG1 and then added moDCs in the presence of IFNγ. After 48 hours, IFNγ-treated moDCs alone produced low levels of TNF (Figure 4E). moDCs cultured in IgG2c-coated wells produced significantly more TNF than IgG1, supporting a more proinflammatory effect on these cells (Figure 4E). Next, we made antibody-coated particles (that could mimic antibody-coated oxLDL or necrotic debris in plaques) using polystyrene beads coated with IgG2c or IgG1. Coated beads (or control uncoated beads) were incubated with IFNγ-pretreated moDCs and TNF production quantified. Uncoated beads induced some TNF production above IFNγ-treated moDCs without beads (Figure 4F); however, IgG2c-coated beads produced increased TNF, whereas IgG1-coated beads did not (Figure 4F). These data support the notion that IgG2c antibodies could enhance inflammatory responses by plaque macrophages or dendritic cells.

B cell FcγRIIB Overexpression in Female Mice Decreases IgM and Enhances Atherosclerosis

We were initially surprised that IgM levels were not modulated in Btg mice because FcγRIIB should also negatively regulate IgM+ plasma cells and has also been shown to promote B-1 cell apoptosis. Indeed, when we purified B-1 cells from Btg Apoe−/− mice and incubated them in control or anti-FcγRIIB–coated plates, Btg Apoe−/− B cells were more prone to undergo apoptosis (Figure VIA in the online-only Data Supplement; assessed by Annexin V exposure; see Methods). This suggests that in vivo in male Bsg mice, the pool of IgM-secreting B-1 cells or other IgM-producing B cells was renewed rapidly enough from resting B cells to compensate for a shorter lifespan of IgM antigen-secreting cells. However, when we investigated female Bsg Apoe−/− mice, we did observe a reduction in B-1 cells, total IgM levels, and MDA-LDL IgM levels (Figure 5A through 5C), with other B cell parameters similar to males (data not shown). Indeed, as the major observed difference between genders, the reduced IgM in females seems to be critical to the outcome of atherosclerotic plaque development because female Bsg Apoe−/− had significantly enhanced atherosclerosis (Figure 5D) in contrast to the male counterparts (Figure 1) but similar to antibody-deficient Xbp1−/− mice and B cell (and therefore antibody)−deficient mice. The plaques of Bsg Apoe−/− female mice had larger necrotic cores (Figure VIB in the online-only Data Supplement). Therefore, a combined deficiency in IgG and IgM may provide an explanation for the accelerated atherosclerosis in female mice in this setting.

Male and Female Apoe−/− Mice Display Different B-1 Cell Dynamics In Vivo and In Vitro

We investigated several possibilities that could explain the sex disparity. There was no sex-specific difference in FcγRIIB overexpression levels in Bsg mice or in baseline FcγRIIB levels in control littermates on B-1 cells (Figure VIC in the online-only Data Supplement). We did observe, by analyzing past data from multiple experiments and strains on the Apoe−/− background, that female Apoe−/− mice had higher B-1 cell numbers in the spleen (Figure 6A). A higher proportion of female B-1 cells stained positive for the proliferation marker Ki67 than in male B-1 cells in the spleen (Figure 6B), where B-1 cells migrate to self-renew or differentiate into plasma cells. Despite the difference in splenic B-1 cell levels
between males and females, which was highly reproducible, there were no consistent differences in total or oxidation-specific epitope–specific IgM levels or IgM-producing plasma cells between male and female Apoe−/− mice (data not shown). We hypothesized that a larger supply of B-1 cells is required to maintain similar steady-state levels of IgM in females than in males, at least in the context of the high demand expected in atherosclerotic mice, where splenic B-1 cells and IgM levels expand compared with WT mice. This could then provide an explanation why in B<sup>+</sup> mice, where there is even further pressure on B-1 cell numbers, a difference in B-1 cells and IgM levels is seen in females not males. This higher turnover in females could be explained by a higher clearance/degradation rate of IgM or a shorter lifespan of B-1 plasma cells. First, IgM clearance rate was investigated by transferring serum with antibodies of the “a” heavy chain isotype (from Balb/c mice) into Apoe<sup>−/−</sup> mice, which express the “b” heavy chain isotype, allowing quantification of injected IgM<sup>a</sup> by ELISA. The clearance of IgM<sup>a</sup> was tracked over 48 hours, but we did not observe a difference in half-life between male and female Apoe<sup>−/−</sup> mice (Figure VID in the online-only Data Supplement). Second, in vitro, we assessed the ability of male and female B-1 cells to form IgM-secreting plasma cells in response to IL-5 and BAFF. We found a decreased ability of female B-1 cells to produce IgM compared with males (Figure 6C and 6D). Female B-1 cells showed enhanced susceptibility to apoptosis, with fewer female B-1 cells than male B-1 cells alive after overnight culture (staining negative for Annexin V and propidium iodide; Figure 6E). Elispot assays for IgM demonstrated that female IgM antigen-secreting cell produce similar amounts of IgM per cell (spot size; Figure VIE in the online-only Data Supplement).

Female FcγRIIb<sup>bAP1</sup> mice were also different from male counterparts. Despite a similar decrease (to that seen in males) in FcγRIIb levels on GC B cells of female FcγRIIb<sup>bAP1</sup> mice compared with control littermates (Figure VIIA in the online-only Data Supplement), there was no difference in proportions of GC B cells (Figure VIIB in the online-only Data Supplement), total IgG2c (Figure VIIIC in the online-only Data Supplement), and total IgM (Figure VIID in the online-only Data Supplement), and consequently no difference in atherosclerosis (Figure VIIE in the online-only Data Supplement). Female Apoe<sup>−/−</sup> mice had higher proportions of GC B cells (compare Figure 3B and Figure VIIB in the online-only Data Supplement), follicular helper T (Figure VIIF in the online-only Data Supplement), increased anti-dsDNA autoantibodies (Figure VIIG in the online-only Data Supplement), and increased IgG2c antibodies (Figure VIHI in the online-only Data Supplement) compared with males, suggesting an already enhanced autoimmune susceptibility that may not be increased so easily as in the males by the FcγRIIb mutation.

Discussion

Systemic and local inflammation is increasingly accepted as a major independent driver of atherosclerotic cardiovascular disease. Inflammation can induce and accelerate autoimmune responses that contribute to local tissue damage and prevent resolution. Here, we report the novel finding that B cell–intrinsic control of autoimmune GC responses by the IgG receptor FcγRIIB limits atherosclerotic plaque development in mice. Although a role for FcγRIIB has been previously reported, the influence and mechanism, and in particular the main cell type expressing FcγRIIB, are not understood. Our results support a pathogenic role for GC-dependent responses, and we propose that IgG2c class switching may be a key pathogenic pathway. In addition, (1) we reveal a potential explanation for the opposite effects on atherosclerosis observed in FcγRIIB<sup>−/−</sup> mice and other models modulating both B-1 and B-2 cells and (2) provide further support for the paradigm that autoimmune responses in mouse atherosclerosis, like in humans, are sex-dependent.

Our study is the first to reveal the importance of B cell FcγRIIB in experimental atherosclerosis. In addition to plasma cell responses, FcγRIIB also controls the GC response and is especially important in limiting access by autoreactive B cells. Data from both models suggest that GC-dependent responses may promote atherosclerosis, consistent with previous data implicating the GC as pathogenic. Overexpression of FcγRIIB led to a decrease in GC B cells and GC-dependent
IgG isotypes (Figure 2). More specifically, limiting FcγRIIib upregulation on GC B cells but not plasma cells, B-1 cells or marginal zone B cells led to increased atherosclerosis, associated with an enhanced GC response (Figure 3). Crucially, in FcγRIIib−/− mice, we were not able to detect differences in effector T cell responses (except GC-promoting follicular helper T) and only observed an increase in IgG2c antibodies, not IgG1. The latter effect may reflect the relatively short duration of the experiments, Th2-dependent IgG1 responses being more prevalent after prolonged high-fat diet.40 IgG2c is known not IgG1. The latter effect may reflect the relatively short duration of helper T cell responses (except GC-promoting follicular RIIA. 11 Recently, a subset of human γRIIIA (CD16), be the most responsive to immune prolif FcγRIIib deficiency was a key player in that study. Sex was important in 1 study using Fcγ2b−/− mice, as observed in our study, but a similar effect was observed in both genders in another study. Since the anti-inflammatory pathways listed above are not B cell intrinsic, they are likely to have different sex dependency. For example, IFNγ deficiency only reduced atherosclerosis in male but not in female mice.48 Here, we found that modulation of IgM levels occurred only in female B8 mice despite a similar effect in both males and females on FcγRIIib overexpression. FcγRIIib appeared less important for the GC response in females, which might be explained by the already increased GC levels and autoantibodies, consistent with the enhanced susceptibility to autoimmunity of females, both in mice and in humans.49 Both estrogen and testosterone have been implicated in regulating B cells. For example, a recent study demonstrated that testosterone regulation of BAFF production in the spleen is important in regulating the B cell compartment,50 and a complement-independent natural antibody pathway for bacterial clearance is driven by estrogen and is only effective in females.51 In humans, Frostegård et al52 report higher antiphosphorylcholine IgM levels in females in multiple cohorts. Further studies investigating the differences between male and female B cell systems, in particular, B-1 cells, will be necessary to better understand the sex-dependent regulation of B cell responses in atherosclerosis.

In summary, our studies make further strides toward understanding B cell regulation of atherosclerosis and support the pathogenic involvement of an active, Th1-polarized GC-dependent response controlled by FcγRIIib levels. Our data further support an important influence of B-1 cell–derived IgM but also now suggest the relative importance of these responses is sex dependent. Given the enhanced adaptive response associated with vulnerable plaques,53 targeting such responses may be a future therapeutic strategy.

---

**Highlights**

- The inhibitory IgG receptor FcγRIIB (Fcγ receptor IIb) controls B cell activation and plasma cell survival.
- In atherosclerotic mice, specific modulation of B cell FcγRIIB expression levels reveals FcγRIIB suppresses a pathogenic (and proatherogenic) germinal center B cell response in male mice.
- Germinal center B cells produce IgG2c antibodies that promote TNF (tumor necrosis factor) production by monocyte-derived macrophages/dendritic cells via FcγRIIB, equivalent to IgG1-FcγRIIIA in humans.
- FcγRIIB also controls atheroprotective B1-cell responses; in female atherosclerotic mice, this function is more dominant and FcγRIIB overexpression resulted in enhanced atherosclerosis.
