Abstract Luminal activation of protease-activated receptors-2 (PAR2) on colonocytes by trypsin or PAR2-activating peptide increases colonic paracellular permeability (CPP). The aim of this study was to evaluate the role of proteases from endogenous and bacterial origin in the modulation of CPP and colonocyte PAR2 expression in mice. CPP was assessed with $^{51}$Cr-EDTA after intracolonie administration of different protease inhibitors. After 12 days of oral antibiotic treatment, measurements of colonic luminal serine protease activity (CLSPA), CPP, mucosal mouse mast cell proteinase-1 (MMCP-1) content, immunohistochemistry of PAR2 and assessment of effects of PAR2 agonist (SLIGRL) and mast cell degranulator (C48/80) on CPP in Ussing chambers were performed. Immunohistochemistry was repeated after intracolonie trypsin administration. Colonic infusion of protease inhibitors significantly reduced CPP. In antibiotic-treated mice, CLSPA was reduced coupled with a decrease in PAR2 expression, but with no change in CPP and MMCP-1 content. Trypsin administration restored PAR2 expression. The increase in CPP induced by SLIGRL and C48/80 was reduced after antibiotic treatment. Protease activity of colonic content plays an important role in the regulation of mucosal barrier through activation of PAR2.

Keywords antibiotic treatment, colonic paracellular permeability, mouse mast cell proteinase-1, protease-activated receptor-2, protease inhibitor, Ussing chamber.

INTRODUCTION

Protease-activated receptors (PARs) belong to a family of seven transmembrane domain G-protein-coupled receptors that are activated by the cleavage of their N-terminal domain by a proteolytic enzyme. The unmasked new N-terminal sequence acts as a tethered ligand that binds and activates the receptor itself. PARs are expressed throughout the gastrointestinal tract on several cell types, as enterocytes, mast cells, smooth muscle cells, myenteric neurons and endothelial cells. Moreover, a preliminary immunohistochemical study indicates that PAR2 are mainly localized on the apical site of colonic epithelial cells. In vivo, intracolonie activation of PAR2 leads to colonic inflammation in mice and increases paracellular permeability with bacterial translocation into peritoneal organs. PAR3 activation results in downregulation of the receptor at the apical sites of colonocytes followed by an upregulation prominently in the intracellular compartments in crypts. In mice, intracolonie infusion of low-dose PAR2-activating peptide (SLIGRL) increases colonic paracellular permeability (CPP) by a direct myosin-light chain kinase (MLCK)-dependent mechanism. PAR2 activation-induced colitis is dependent on sensory neuron activation, substance P and calcitonine gene related peptide release. Overexpression of PAR3 was observed in biopsies from inflammatory bowel disease (IBD) patients, suggesting a pathophysiological role of PAR2 in the development of colonic inflammation. Recent preliminary works demonstrated an increased trypsin-like proteolytic activity in colonic biopsies from irritable bowel syndrome (IBS) patients. This protease activity was able to cause hyperalgesia when injected into mouse paws thoroughly a mechanism involving PAR2 activation. In spite of
growing evidence of the important role of PAR2 in pathological conditions, the physiological role of PAR2 located on colonocytes remains unclear.

Proteases are present in great amount in the gastrointestinal tract. In addition to their digestive role in protein degradation, they play a role as signalling molecules regulating cell functions by cleaving PARs. PARs are activated by a variety of proteases, such as digestive enzymes [trypsin and trypsinojen], proteases released from mast cells and neutrophils, and by proteases of the coagulation cascade. Proteases of human pathogen Porphyromonas gingivalis activate PARs on human oral epithelial cells, neutrophils and platelets. Even though resident colonic bacteria release considerable amount of proteases, no studies have already evaluated the effects of intestinal bacterial flora on PAR activation. All these data let us to hypothesize that bacterial proteases or at least luminal proteases of the cited origins may also act on PARs on colonocytes, and may affect CPP by modulating the degree of PAR2 activation.

The present study is aimed (i) to evaluate if intraluminal proteases and particularly serine proteases play a role in the physiological control of paracellular permeability by infusing intracolonically a mixture or selective protease inhibitors, (ii) to determine more specifically the role of proteases from bacterial origin in the regulation of colonic barrier function and (iii) to assess the role of proteases from mast cells in colonic PAR2 activation.

MATERIALS AND METHODS

Animals

Male Swiss 3T3 and C57BL/6 mice were obtained from Janvier (Le Genest St-Ise, France). Mice were housed in polycarbonate cages in a light (12 h/12 h cycle)- and temperature-controlled room (20–22 °C) and were fed standard pellets [UAR pellets, Epinay, France]. Water was provided ad libitum. The experimental protocols described in this study were approved by the local Institutional Animal Care and Use Committee.

Intracolonic injections

Mice were fasted for 12 h before intracolonic injections. Under mild xylazine/ketamine (10 and 2 mg per mouse, respectively, subcutaneously) anaesthesia, a small polyethylene catheter [0.3/0.07 mm] was inserted intrarectally at 4 cm from the anus. Trypsin, saline and protease inhibitors were injected into the distal colon through the catheter.

Experimental protocol

For the assessment of the effect of protease inhibitors on CPP, five groups of Swiss 3T3 mice (n = 8–8) received an intracolonic infusion (250 μL h⁻¹) of a mixture of water-soluble protease inhibitors with a broad specificity for the inhibition of serine-, cysteine-, aspartic- and metalloproteases [100 μg mL⁻¹, Protease Inhibitor Cocktail for General Use, Sigma; St Quentin Fallon, France], cysteine protease inhibitor [100 μg mL⁻¹, cystatin, Sigma], serine protease inhibitor [100 μg mL⁻¹, aprotinin, Sigma], matrix metalloprotease inhibitor [100 μg mL⁻¹, galardin, Sigma] or saline for 5 h. Paracellular permeability was assessed during the last 2 h of protease inhibitor treatment.

Four groups of Swiss 3T3 mice and six groups of C57BL/6 mice (n = 8–8) were used for studies on antibiotic treatment, respectively. Three groups of Swiss mice and three groups of C57BL/6 mice were treated for 12 days with antibiotics (0.5 g L⁻¹ ampicillin and 1 g L⁻¹ neomycin in drinking water). Preliminary experiments, we verified that these antibiotics had no direct effect on CPP in Ussing chambers (data not shown). One group of Swiss and three groups of C57BL/6 mice were used as control. One group of antibiotic treated and one control group of Swiss 3T3 mice were killed at day 12 for the measurement of serine protease activity in colonic luminal contents and immunohistochemistry of PAR2 in colonic mucosa. In two groups of antibiotic-treated Swiss 3T3 mice, immunohistochemistry of PAR2 was performed after the animals received daily intracolonically [50 μL] trypsin [400 U per mouse] or saline for 2 days under the antibiotic treatment. Two groups of antibiotic-treated and two control groups of C57BL/6 mice were killed at day 12 for the in vitro measurement of colonic permeability in Ussing chambers, in basal conditions and after administration of PAR2-activating peptide (SLIGRL) or mast cell degranulator [compound 48/80]. Furthermore, one group of antibiotic-treated and one control group of C57BL/6 mice were killed at day 12 for the measurement of mouse mast cell protease-1 (MMCP-1) content of colonic mucosa.

Serine protease activity in colonic content

Colonic content was obtained by rinsing the entire colon with 1 mL of saline. This solution was transferred to 4 mL of reaction buffer containing 0.15 mol L⁻¹ NaCl and 20 mmol L⁻¹ Tris-HCL. Coarse particles were removed from this solution by filtration with 0.8-μm size syringe filter [Nalgene, Nalge, NY, USA] after centrifugation at 4500 g for 10 min at 4 °C. Samples of 25 μL from the supernatant
were incubated with 1 mL of reaction buffer and 1 mL of 0.5% [w/v] azocasein (Sigma) at 40 °C for 20 min. The reaction was stopped by the addition of 1 mL of 10% [w/v] trichloroacetic acid (TCA; Sigma). After centrifugation at 4500 g for 10 min at 4 °C, absorption of the clear supernatant was measured at 366 nm and compared with standard curves obtained from a titration series of azocasein. The protein content of the filtered supernatant of colonic content was assessed with BCA-200 Protein Assay Kit [Pierce, Rockford, IL, USA], with bovine serum albumin (BSA) as a standard. Serine protease activity was expressed as units of trypsin activity in mg of total proteins (U mg⁻¹).

**Immunohistochemistry of PAR₂**

Colonic samples were fixed 12 h in 4% formalin, dehydrated through graded ethanol and embedded in paraffin. Sections (5 μm) were rehydrated and submerged in antigen retrieval solution [citrate buffer, 10 mmol L⁻¹, pH 6, 95 °C, 3 min]. After inhibition of endogenous peroxidases with 0.6% H₂O₂ in 100% methanol for 30 min and incubation in blocking solution [phosphate buffered saline (PBS) containing 1% BSA and 2% goat normal serum], sections were incubated with rabbit PAR₂ antibody [supplied by M. D. Hollenberg] overnight, +4 °C followed by a biotinylated goat anti-rabbit IgG immune serum [30 min, room temperature] and subsequently with avidin-biotin complex complexes coupled to peroxidase [Vectastain Elite ABC kit, AbCys, Paris, France]. Antigen-antibody complexes were revealed using 3,3′-diaminobenzidine (DAB kit, ICN Pharmaceuticals, Costa Mesa, CA, USA). Hemalum was used as a counterstain. As negative controls, sections were treated with the same procedure except for the absence of primary antibody.

**Immunohistochemical analysis**

Immunohistochemical analysis was performed in a blinded fashion using a Nikon 90i microscope. PAR₂ expression was quantified employing the software UMA C A G (version 4.8, Nikon, Champigny-sur-Marne, France) measuring the mean density per square micrometre of colonic epithelium. All analyses were performed on 10 fields per sample.

**In vitro permeability studies**

C57BL6 mice were killed by cervical dislocation. The distal colon was removed and two colonic strips from each mouse were mounted in Ussing-type chambers [Easymount, Hamden, CT, USA] having a flux area of 0.3 cm². Both sides of each colonic sheet were bathed in 5 mL of Krebs solution which was maintained at 37 °C and oxygenated continuously with 5% CO₂ in O₂. Permeability was assessed by measuring mucosal to serosal fluxes of fluorescein isothiocyanate (FITC)–dextran across the colonic strip. For the assessment of PAR₂ responsiveness, the FITC–dextran flux was determined 1 h after the administration of SLIGRL or its vehicle [saline]. For the measurement of the effect of mast cell degranulation, the FITC–dextran flux was evaluated 1 h after the administration of compound 48/80 or its vehicle [water]. In brief, after a 20 min equilibrium period 550 μL of buffer solution on the mucosal side was replaced by 500 μL of FITC–Dextran [10 000 MW, 0.022 g] and 50 μL of SLIGRL [25 μmol L⁻¹], saline, compound 48/80 [10 μg mL⁻¹] or water. After 30 and 60 min, 800 μL solution from the serosal side was removed and fluorescence was measured on fluorimeter (Luminescence Spectrometer LS 50 B, Perkin Elmer, Wellesley, MA, USA). The FITC–dextran flux was expressed as quantity of FITC–dextran that crossed 1 cm² in 1 h (nmol h⁻¹ cm⁻²).

**ELISA for MMCP-1**

C57BL6 mice were killed by cervical dislocation. The distal colon was removed and the colonic mucosa was carefully removed with a dissector. The mucosal samples were homogenized in RIPA buffer (Roche Diagnostics, Basel, Switzerland) and centrifuged at 10 000 g at 4 °C. Supernatants were used for the MMCP-1 and total protein content measurements. MMCP-1 ELISA assays were performed with MMCP-1 ELISA Kit [Moredun, Midlothian, UK]. Dynatech M129B 96-well plates [Dynatech, Plochingen, Germany] were coated for 24 h at 4 °C with 2 μg/mL of affinity-purified sheep anti-MMCP-1 Ig in carbonate buffer (pH 9.6). Wells were washed [6×] with PBS and 0.05% [v/v] Tween 20.
Standard (0.25-12 ng mL⁻¹ of purified MMCP-1) and samples were applied [50 μL per well], diluted as appropriate in PBS containing 4% BSA and 0.05% (v/v) Tween 20. After incubation in room temperature for 1.5 h, plates were washed as above and incubated for 1 h at room temperature with 50 μL per well of rabbit anti-MMCP-1-horseradish peroxidase conjugate [diluted as appropriate in PBS containing 4% BSA and 0.05% (v/v) Tween 20]. Plates were washed and incubated for 25 min at room temperature with 50 μL per well ortho-phenylene diamine/H₂O₂ substrate. The reaction was stopped with 25 μL per well 2.5 mol L⁻¹ H₂SO₄. Plates were read at 492 nm on Microplate Reader. The standard curve was generated and sample concentrations were calculated using software [Microplate Manager 5.2.1, Bio-Rad, Marnes-La-Coquette, France]. Protein concentration was determined with a commercial kit [BCA-200 Protein Assay Kit; Pierce] MMCP-1 content of colonic mucosa was expressed as ng of MMCP per gram of total proteins.

**Chemicals**

SLIGRL-NH₂ prepared by solid-phase synthesis was obtained from Neosystem [Strasbourg, France]. The composition and purity of peptides were confirmed by HPLC analysis. Trypsin, neomycin sulphate, compound 48/80, the mixture of serine protease inhibitors [Protease Inhibitor Cocktail for General Use containing 4-[2-aminoethyl]-benzenesulphonyl-fluoride, E-64, bestatin, leupeptin, aprotinin, Na-EDTA], cysteine protease inhibitor [cystatin from chicken egg white lyophilized powder], serine protease inhibitor [aprotinin] and the matrix metalloprotease inhibitor galdarin, N-[23]-[methoxy-carbonylmethyl]-4-methylpentanoyl]-L-tryptophan-methylamide were obtained from Sigma. Ampicillin was obtained from Euromedex [Souffelweyersheim, France]. SLIGRL was dissolved in saline, compound 48/80 was dissolved in distilled water, neomycin and ampicillin were dissolved in tap water.

**Statistical analysis**

Data are presented as means ± standard error of the mean. Analyses were carried out by running the GraphPad Prism 4.0 software (GraphPad, San Diego, CA, USA). All data were normally distributed. Between-group comparisons were performed by Student’s unpaired t-test. Multiple comparisons within groups were performed by repeated measures one-way ANOVA, followed by Student’s t-test. Statistical significance was accepted at P < 0.05.

**RESULTS**

*In vivo* gut paracellular permeability

In anaesthetized mice, basal gut permeability measured for 2 h after intracolonic saline administration was 2.2 ± 0.1% of total ^51^Cr-EDTA recovered. Intracolonic administration of a mixture of antiproteases reduced this basal value to 1.1 ± 0.2%. Aprotinin, a serine protease inhibitor, reduced the basal colonic permeability to 1.1 ± 0.1%. Galardin, a matrix metalloprotease inhibitor, significantly decreased CPP compared with saline perfusion (0.9 ± 0.2% vs 2.2 ± 0.1%) (P < 0.01). In contrast, only cystatin, a cysteine protease inhibitor, had no effect on CPP (2.1 ± 0.2%) (Fig. 1).

In mice treated with antibiotics during 12 days, the CPP was not significantly changed when compared with control animals (1.1 ± 0.1% vs 1.0 ± 0.1%) (Fig. 2).

![Figure 1](image1.png)

**Figure 1** Effect of intracolonic infusion of antiprotease cocktail, selective cysteine- (cystatin), serine- (aprotinin) and matrix metalloprotease inhibitors (galardin) on colonic paracellular permeability. Inhibitors were infused at a dose 50 μg 2 h⁻¹ per mouse. Values are means ± SEM. *P < 0.01, significantly different from controls (saline infusion).

![Figure 2](image2.png)

**Figure 2** Effect of antibiotic treatment on colonic paracellular permeability (*in vivo*). Values are means ± SEM.
Serine protease activity of colonic contents

In fasted control Swiss mice, the serine protease activity of colonic content was 48.4 ± 9.5 U mg⁻¹ of total proteins. A oral antibiotic treatment for 12 days reduced the serine protease activity of colonic content to 9.6 ± 7.0 U mg⁻¹ of total proteins [P < 0.01] (Fig. 3).

PAR₂ immunohistochemistry

Basal PAR₂ immunohistochemistry showed prominent immunostaining of colonocytes (optical density: 0.3 ± 0.1). In antibiotic-treated mice, PAR₂ immunostaining was significantly attenuated (optical density: 0.2 ± 0.1) when compared with control animals [P < 0.01]. Under antibiotic treatment, 2 days of daily intracolonic administration of trypsin restored the PAR₂ immunoreactivity (optical density: 0.3 ± 0.1) [Fig. 4Aa,B].

In vitro gut permeability

Control values of dextran sulphate flux significantly increased after the application of PAR₂ agonist, SGLGL to the mucosal site (1.4 ± 0.5 vs 4.1 ± 0.7 nmol h⁻¹ cm⁻²; P < 0.05). Colonic strips collected from animals treated with antibiotics exhibit dextran sulphate flux similar to that observed in strips collected from controls (1.4 ± 0.1 nmol h⁻¹ cm⁻²); however, antibiotic treatment for 12 days significantly reduced the effect of SGLGL on colonic permeability (2.1 ± 0.4 nmol h⁻¹ cm⁻²) [Fig. 5]. Administration of compound 48/80 resulted in a significantly higher increase [P < 0.05] in colonic permeability in control animals (5.9 ± 0.6 vs 1.9 ± 0.3 nmol h⁻¹ cm⁻²; P < 0.01) when compared with the antibiotic-treated mice (3.6 ± 0.4 vs 2.2 ± 0.3 nmol h⁻¹ cm⁻²; P < 0.05) [Fig. 6].

MMCP-1 content of colonic mucosa

In control mice, the MMCP-1 content of colonic mucosa was 4.6 ± 0.7 ng g⁻¹ of total proteins. After 12 days of antibiotic treatment, MMCP-1 content was not significantly changed (4.1 ± 0.9 ng g⁻¹ of total proteins) when compared with control values (Fig. 7).

DISCUSSION

This study provides new evidence that luminal proteases regulate CPPP in physiological conditions and that colonic microflora affects colonocyte PAR₂ expression possibly through luminal protease activity. We also evidence that colonic bacterial flora influences mucosal mast cell degranulation, but not the release of mast cell protease into the colonic lumen, suggesting a limited role of secreted proteases from mast cells in the regulation of epithelial cell PAR₂ expression probably regulated only by luminal proteases.

Protease-activated receptors are highly expressed in the gastrointestinal tract. Among others, they are present in colonic epithelial cells. Proteases from endogenous or bacterial origin can activate PARs. Trypsin and trypsinogen released from digestive glands and epithelial cells, thrombin, factors VIIa and Xa from coagulation cascade and cathepsin G, elastase or protease 3 released from neutrophils are potential activators of PARs. Bacteria have both protease and antiprotease activity. Indeed, Porphyromonas gingivalis, a pathogen bacterium in the oral cavity, a mediator of periodontal disease, releases arginine-specific protease (gingipain) which can activate PAR₁, PAR₂ and PAR₃. Clinical studies have shown an elevated colonic protease activity and PAR₂ in intestinal inflammation; however, until now, the physiological role of intraluminal proteases and PAR₂ in the control of colonic barrier function has been unexplored.

In a previous study, we have shown that low dose of SGLGL infused intracolonically activated PAR₂ and increased paracellular permeability to macromolecules in vivo through calmodulin and subsequent MLCK activation provoking tight junction opening by perijunctional ring myosin phosphorylation. Intracolonic administration of higher dose of SGLGL also caused...
Figure 4  [A] Effect of antibiotic treatment on colonic protease activated receptor-2 (PAR2) immunostaining. PAR2 immunoreactivity (brown) in colonic sections of control animals (a1, a2, a3), antibiotic treated animals (b1, b2, b3) and animals received daily intracolonic trypsin injections during the antibiotic treatment (c1, c2, c3). [B] Effect of antibiotic treatment on colonic PAR2 immunohistochemistry. Data (means ± SEM) are expressed as total number of grey levels per square micrometre of colonic mucosa. *P < 0.01, significantly different from control mice and animals received daily intracolonic trypsin injections during the antibiotic treatment.
colonic inflammation partly independently of paracellular permeability. Mast cell serine proteases,\textsuperscript{19} neutrophil serine proteases\textsuperscript{19} and Bacteroides fragilis metalloprotease\textsuperscript{20} are known to increase intestinal permeability. However, colonic digestive enzymes are potent activators of PAR\textsubscript{4}\textsuperscript{15,16} and although intracolonic administration of selective PAR\textsubscript{4} agonist increases CPP,\textsuperscript{3,4} no studies have already reported the physiological effect of digestive enzymes on colonic barrier function. Our study is the first to investigate the effect of different luminal proteases on colonic barrier function. We have shown that intraluminal delivery of protease inhibitors decreases CPP.

In the colon, resident bacteria release serine proteases, and other proteases and the digestive enzymes are partly degraded by host-proteases and bacterial peptide hydrolases.\textsuperscript{21,22} Therefore, the pathogenic and non-pathogenic bacteria are considerably responsible for the luminal proteolytic activity. Although substantial proportion of colonic intestinal proteases is of bacterial origin, no evidence reported about the effect of colonic bacteria on PAR function. We demonstrated that the reduction of resident colonic bacteria by antibiotic treatment decreases the serine protease activity of the colonic content coupled with a decrease in PAR\textsubscript{3} expression in colonic mucosa. The effect on PAR\textsubscript{3} expression is specific for the protease activity of the colonic content, because daily colonic administration of a serine protease restores PAR\textsubscript{3} expression of colonocytes. However, in contrast to that observed with serine protease inhibitors, we did not find any significant change in colonic paracellular permeability after broad-spectrum antibiotic treatment, despite the downregulation of PAR\textsubscript{3} and the reduced protease activity. A possible explanation for this phenomenon is that changes in PAR\textsubscript{3} expression and in protease activity occur slowly during the 12 days of treatment given rise to compensatory mechanism regulating CPP.

Tryptase released from mast cells may activate PAR\textsubscript{3} located on epithelial cells directly on basolateral site.\textsuperscript{23} Increased mast cell tryptase release was found in colonic biopsies proven from ulcerative colitis patients,\textsuperscript{24} moreover, increased mast cell density was observed in colonic biopsy specimens of IBS patients\textsuperscript{25-27} and supernatant from colonic biopsies of IBS patients injected into paw of rats induced sensitization to pressure stimulus through PAR\textsubscript{3} activation.\textsuperscript{8} Although mast cells localized in close contact with the external environment play an important role in the response to pathogen intestinal bacteria,\textsuperscript{28,29} the effect of non-pathogen resident intestinal microorganisms on mast cell function is not clear. We
found that changes in resident bacterial flora following oral antibiotic treatment decreased colonic mast cell degranulation; however, colonic mucosal mast cell protease-1 content remained unchanged. Through the bidirectional cross-talk between mast cells and PAR2, the explanation of decreased mast cell degranulation after the modification of colonic flora could be dual. The decreased sensitivity of mast cells to degranulate related to changes in colonic bacterial stimulation could result from a decrease in PAR2 expression of colonicocytes; however, the decrease of mast cell degranulation could be the result of decreased PAR2 responsiveness of mast cells mediated by change of colonic luminal protease activity.

Intestinal permeability plays a key role in the pathogenesis of different gastrointestinal disorders. Increased intestinal permeability has been described in patients with Crohn’s disease, and in symptom-free, healthy relatives of Crohn’s disease patients. Increased intestinal permeability is also a predictor of relapse in patients with Crohn’s disease. Postinfectious IBS is also associated with an increase in intestinal permeability. Alterations of visceral sensitivity provoked by acute partial restraint stress depends upon the increase in CPP. Similarly, intracolonic infusion of subinflammatory doses of PAR agonist produces a delayed rectal hyperalgesia that involves an increase in intestinal permeability in rats. Our study showed that colonic serine proteases regulate CPP supporting the hypothesis that a high level of intraluminal proteases may play a role in the development of colonic inflammation and visceral hyperalgesia.

Finally, our data indicate that luminal proteases regulate CPP in physiological conditions and modification of colonic bacterial flora affects colonicocyte PAR2 expression and sensitivity of mast cells to degranulate. Therefore, it leads us to speculate that changes in intraluminal protease activity linked to alterations of colonic microflora and/or proteolytic enzyme secretion may play a role in the genesis of visceral hypersensitivity and IBS symptoms.
