Abstract—This paper proposes a method for direct torque control of Brushless DC (BLDC) motors. Evaluating the trapezium of back-EMF is needed, and is done via a sliding mode observer employing just one measurement of stator current. The effect of the proposed estimation algorithm is reducing the impact of switching noise and consequently eliminating the required filter. Furthermore, to overcome the uncertainties related to BLDC motors, Recursive Least Square (RLS) is regarded as a real-time estimator of inertia and viscous damping coefficients of the BLDC motor. By substituting the estimated load torque in mechanical dynamic equations, the rotor speed can be calculated. Also, to increase the robustness and decrease the rise time of the system, Modified Model Reference Adaptive System (MMRAS) is applied in order to design a new speed controller. Simulation results confirm the validity of this recommended method.

Index Terms— Brushless DC Motor, Direct Torque Control, Model Reference Adaptive System, Sliding Mode Observer

I. INTRODUCTION

Synchronous motors are gaining much attention compared with induction motors [1-6]. Brushless DC (BLDC) motors are classified as synchronous AC electric motors, which play a significant role in contemporary applications, such as: industry, transportation, visual and sound equipment in medical applications, with a large variety of power ranges. Preferable speed-torque features, great dynamic response, long life cycle, noiseless action, and broad speed dimensions are the advantages of BLDC motors compared with brushed DC and induction motors.

One of the most ubiquitous control drives of BLDC motors is Direct Torque Control (DTC), which has been presented in [7,8]. It is worth mentioning that the conventional DTC method, which has been presented for Permanent Magnet Synchronous Motors (PMSMs), cannot be employed for BLDC motors. The DTC in BLDC motors is simple with high dynamic torque responses and low sensitivity to parameter variations.

BLDC motors operate in either a constant current region or a constant power region. The raising in phase current and consequently output torque can devastate the control drives algorithm in a constant torque region. However, in a constant torque region, the BLDC motor’s back-EMF is less than the DV voltage of the inverter, which can prevent phase current rise. Therefore, in this study the simulations are based on the constant torque operating region.

Commutation has to be done at exact rotor positions for efficient performance. Hence, six discrete rotor positions should be considered to feed BLDC motors with rectangular phase currents. Although Hall sensors are the best type of sensors for BLDC motors due to soft starting, it has several drawbacks, such as: cost, sensitivity to the temperature, and unreliable performance in industrial areas. To overcome these problems diverse approaches have been addressed in articles [9-16]. For example, the proposed methods for folding trace technique of Magnet Resistors as well as shielding for Hall effect sensing element [17] could enhance bandwidth for advanced current controlling schemes. Other approaches include mechanisms based on integration and third harmonics of back-EMF, flux and terminal voltage calculation, and discovery of freewheeling diodes.

For BLDC motors, sensorless operation is one of the effective methods in speed-dependent back-EMF. However, this method has its own drawbacks, such as low performance in low speed BLDC motors, and position error at the estimated commutation point.

Extended Kalman Filter (EKF) and sliding mode algorithms are presented in [18-23]. The drawbacks of EKF are: noise influence, complicated configuration, and computation implementation adversity. In contrast, sliding mode observers’ advantages, such as: being appropriate for piecemeal designing, being suitable for non-smooth systems, having firmness against parameters variation, converging in the shortest possible time, and reducing the observation error, has made it an efficient popular method [24]. Therefore, sliding mode observer is employed in the current study. The Recursive Least Square (RLS) is used to estimate the rotor inertia and the viscous damping coefficient [19] so that, the load torque can be estimated. Next, the rotor speed is calculated based on the estimated load torque using mechanical dynamic equations. Finally, measured stator currents, estimated back-EMF, and rotor speed are used to calculate electromagnetic torque.

Model Reference Adaptive System (MRAS) is a closed loop control system and its parameters can be adjusted to decrease the error between actual models and reference models [25, 26]. In this paper, MIT role is employed to design the MRAS. The MRAS is used instead of a PI controller, in order to gain better speed and torque responses.

II. BLDC MOTOR

The sharp distinction between brushed DC motors and BLDC motors is the procedure for commutation. In common DC motors, brushes and mechanical commutators are responsible for commutation, while in BLDC motors, an electronic switching converter performs the commutation. BLDC motors as AC asynchronous motors are designed such
that permanent magnets are located on the rotor surface, and the stator is wire-wound. The exciting process in BLDC motors is because of the permanent magnets as a constant flux source which is called rotor flux. The rotor is the rotating part of a motor and it needs a rotating field, which is provided by stator windings. Hence, by employing the right switching pattern, the perfect rotating field can be supplied. The ideal waveform of back-EMF and currents in BLDC motors with three-phase and 120° conductivity is presented in Fig. 1 [11-13].

The equations of BLDC motors can be depicted as follows:

\[ \begin{bmatrix} V_a \\ V_b \\ V_c \end{bmatrix} = \begin{bmatrix} R_a & 0 & 0 \\ 0 & R_b & 0 \\ 0 & 0 & R_c \end{bmatrix} \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} + \begin{bmatrix} L & 0 & 0 \\ 0 & L & 0 \\ 0 & 0 & L \end{bmatrix} \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} \]

\[ \times \frac{d}{dt} \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} + \begin{bmatrix} e_a \\ e_b \\ e_c \end{bmatrix} \]

In order, \( u_a, u_b, \) and \( u_c \) are the voltages of each phases, while \( i_a, i_b, \) and \( i_c \) are their respective currents. The back-EMF waveforms of phases are named \( e_a, e_b, \) and \( e_c. \) \( R \) and \( L \) are symbols of the resistance and the inductance per phase, and \( M \) shows the mutual inductance per phase. The electromagnetic torque is achieved by:

\[ T_e = \frac{1}{\omega_e} (e_a i_a^* + e_b i_b^* + e_c i_c^*) \]  

(2)

where \( \omega_e \) presents the motor speed. Furthermore, the dynamic motion is obtained by using the following equation:

\[ \frac{d}{dt} \omega_e = \frac{1}{J} (T_e + T_L + B \omega_e) \]

(3)

where \( B \) is the damping coefficient, \( J \) is the motor shaft and load inertias, \( T_e \) is the mechanical torque.

III. DTC IN BLDC MOTORS DRIVE

DTC stands for Direct Torque Control. The history of this control method goes back to 1986, when Takahashi and Noguchi presented this method. The strength of DTC is its ability to control electromagnetic torque and flux linkage simultaneously. Therefore, DTC is the appropriate choice when exact torque control is necessary for BLDC motors. The look-up table in [7] shows the six voltage space vectors which are used to implement DTC. A suitable voltage space vector should be chosen for employing DTC in BLDC motors. Since the torque of BLDC motors should be limited to the hysteresis band by turning off/on transistors, the switching losses are not significant. As noted earlier, the electromagnetic torque quantity plays an important role in the DTC algorithm, especially in a constant torque region. Thus, the final form of the electromagnetic equation in the stationary reference frame is eventuated as [7, 8, 13, 14]:

\[ T_e = \frac{3}{2} P \left( k_d \theta_q i_q + k_i \theta_q i_d \right) \]

(4)

where \( \theta_q \) and \( \omega_e \) are the electrical rotor position and speed, \( k_d(\theta_q), k_i(\theta_q), e_q, e_d, i_q \) and \( i_d \) are back-EMF coefficients, back-EMFs, and stator currents in the stationary reference frame (dq-axes) respectively.

The general configuration of DTC, which is performed in BLDC motors, is demonstrated in Fig.2, which shows several parts such as: a speed controller, an electromagnetic torque estimator, a comparator block for torques, and a switching table. Based on the error between the actual and the reference speed, the reference torque can be calculated. Switching commands, which are instructed to inverters, are based on the hysteresis controller results.

Fig. 1. (a) Structure of drive system in BLDC motor , (b) back EMF arrangement creation of reference current

![Diagram of BLDC Motor Drive System](image)

![Diagram of DTC Configuration](image)

Fig. 2. The general configuration of in BLDC motors drive
Hysteresis control is responsible for correlating real quantities with the commanded torque. To have an appropriate performance, a template for switching is necessary based on flux and torque error, \( F_{\text{st}} \), \( T_{\text{st}} \), respectively. In DTC, both torque and flux are regularly controlled. However, the flux control is not considered in designing the DTC for BLDC motors. Therefore, in switching look-up table, \( F_{\text{st}} \) is set as zero permanently. Consequently, the only effective factor is torque error, which is the discrepancy between the actual and the commanded electromagnetic torque quantity. The number assigned to \( T_{\text{st}} \) (the torque error) is based on the hysteresis control approaches, is proposed [11]. Fig. 3 depicts the general shape of the system in the following order: formation of the system. Three parts are combined together to controller output. For states which the real torque takes less extent than the reference torque in the hysteresis band, \( T_{\text{st}} \) is named "TI" (Increasing Torque). In other cases, it is specified as "TD" (Decreasing Torque). The proper functioning of DTC is expected if the switching table is applied correctly.

### IV. MMRAS SPEED CONTROLLER

In this paper MRRAS, as one of the most noteworthy adaptive control approaches, is proposed [11]. Fig. 3 depicts the general formation of the system. Three parts are combined together to shape the feedback of the system in the following order: processor, controller, and adaption loop. The compared result of the desired model output \( (y_{\text{ref}}) \) and actual system output \( y \) determines the parameters of the controller. The MIT rule is the name of the method which is offered to process error \( e \) in terms of finding controller parameters [27-29]. Fig. 4 illustrates that the plant of the system is eventuated from speed control, and it can be equivalent to a second order system as presented in equation (5).

\[
G_{\text{p}}(s) = \frac{y(s)}{u(s)} = \frac{a}{s^2 + bs + c}
\]

where \( a = R/L + B/J \), \( b = R B /L J \), \( c = k_{\text{p}a} L J /J \) and \( s \) is Laplace operator.

![Fig. 3. Modified model reference adaptive system](image)

The MIT rule is applied to minimize the loss function:

\[
j(\theta) = \sum_{i=1}^{M} \left| \Theta_i - \hat{\Theta}_i \right|^2
\]

In the loss function, \( e \) is a customizable controller parameter. To minimize the loss function, the following equation is employed:

\[
d \theta / dt = - \gamma \delta_j = - \gamma e \delta \theta / \delta \theta
\]

Adaption gain is the name of \( \gamma \). [28]. When calculating sensitivity, which is derivative of controller parameters, the following equations are achieved:

\[
\frac{\delta e}{\delta \theta_1} = \frac{a}{(s^2 + bs + c + a \theta_1)} u
\]

\[
\frac{\delta e}{\delta \theta_2} = \frac{-a \theta_2}{(s^2 + bs + c + a \theta_2)^2} y_{\text{ref}}
\]

The amount of the output control is low in the steady state. So, the \( a \theta_2 \) is insignificant and equations (10) and (11) can be rewritten as:

\[
\frac{\delta e}{\delta \theta_1} = \frac{a}{s^2 + bs + c} u
\]

\[
\frac{\delta e}{\delta \theta_2} = \frac{a}{s^2 + bs + c} e
\]

Considering (12) and (13), the adaption laws are given as:

\[
d \theta_1 / dt = \gamma \frac{a}{s^2 + bs + c} u
\]

\[
d \theta_2 / dt = -\gamma \frac{a}{s^2 + bs + c} e
\]
V. OBSERVER TECHNIQUE

Sliding mode observer is known as a favorable observer of non-linear category observers, and is discussed in detail in [30].

The quality of this method returns to its capability of damping the estimator error quickly. Subsequently, estimates of the observer reconcile with the real outcome of the system. The following equations can be obtained for the BLDC motor (16):

\[
\begin{align*}
\frac{di_{d}}{dt} &= -\frac{R}{L}i_{d} - \frac{1}{L}e_{q} + \frac{1}{L}u_{d} \\
\frac{di_{q}}{dt} &= -\frac{R}{L}i_{q} - \frac{1}{L}e_{d} + \frac{1}{L}u_{q} \\
de_{m} &= 0 \\
de_{ad} &= 0
\end{align*}
\]

(16)

In situations where the electrical and the mechanical time constants are greater than the sampling period, variations of the back-EMF can be negligible within each sampling period [20]. Hence, \( \frac{de_{m}}{dt} = 0 \), \( \frac{de_{ad}}{dt} = 0 \).

Defining \( x_{1} = i_{ad} \), \( x_{2} = i_{d} \), \( x_{3} = e_{d} \), and \( x_{4} = e_{ad} \), the state-space equations of the system given in (6) can be written as follows:

\[
\begin{align*}
x_{1}' &= -\alpha_{1}x_{1} + \alpha_{2}(-x_{3} + u_{1}) \\
x_{2}' &= -\alpha_{1}x_{2} + \alpha_{2}(-x_{4} + u_{2}) \\
x_{3}' &= 0 \\
x_{4}' &= 0
\end{align*}
\]

(17)

In (17), \( u_{1} = u_{d} \) and \( u_{2} = u_{ad} \) are the input variables, \( y_{1} \) and \( y_{2} \) represent the output variables, and \( \alpha_{1} = R/L \) and \( \alpha_{2} = 1/L \) are the system parameters.

The sliding mode observer is proposed as:

\[
\begin{align*}
x_{1}' &= -\alpha_{1}x_{1} + \alpha_{2}(-x_{3} + u_{1}) + k_{s}\text{sat}(x_{1} - \hat{x}_{1}) \\
x_{2}' &= -\alpha_{1}x_{2} + \alpha_{2}(-x_{4} + u_{2}) + k_{s}\text{sat}(x_{2} - \hat{x}_{2}) \\
x_{3}' &= k_{s}\text{sat}(x_{1} - \hat{x}_{1}) \\
x_{4}' &= k_{s}\text{sat}(x_{2} - \hat{x}_{2})
\end{align*}
\]

(18)

The gains of the observer must be determined so that the inequality \( S \cdot \dot{S} < 0 \) is satisfied. To achieve the optimal gains of the observer, the NSGA-II is employed. Fig. 5 demonstrates the configuration of the sliding mode observer. There are several factors, such as unsteadiness, dynamics of the motor, and environmental changes that prevent us from considering parameters B and J as constants. To diminish the repercussions of these fluctuations, the Recursive Least Square (RLS) technique is used. Equation (22) shows the motion control:

\[
y(t) = \phi' \hat{y}(t) \theta(t)
\]

(22)

The RLS rules are [18, 22]:

\[
\dot{\theta}(t) = \dot{\theta}(t - 1) + K(t) [y(t) - \phi'(t) \theta(t - 1)]
\]

(23)

\[
K(t) = P(t - 1)\phi(t)\phi'(t)P(t - 1)\phi(t)^{-1}
\]

(24)

\[
P(t) = (I - K(t)\phi'(t)P(t - 1))P(t - 1)
\]

(25)

where \( \lambda \) is named the forgetting factor. Hence, \( \dot{\theta} \) and \( \dot{\phi} \) are estimated by (23-25). It can be seen in Fig. 6, that \( \dot{\theta} \) and \( \dot{\phi} \) are parameters which are used in load torque estimation. By determining load torque, rotor speed in (3) will be specified. Another parameter is weighting factor \( K \), which is multiplied in estimated load torque to recognize a robust system.

![Fig. 6. Speed observer block diagram](image)

Now all necessary parameters are identified to calculate torque as follows:

\[
\hat{T}_{r} = \frac{3}{2}P \frac{1}{\dot{\omega}_{r}} \phi' (\dot{i}_{ad} + \dot{i}_{d})
\]

(26)

And for electrical position of the rotor, the following equation is used:

\[
\dot{\theta}_{r} = \frac{d}{dt} \hat{\theta}_{r}
\]

(27)

VI. SIMULATION RESULTS

Table 2 shows the parameters of the motor used in simulation.

| Parameter            | Value | Unit  |
|----------------------|-------|-------|
| Number of Poles      | 2     | [pole]|
| DC Link Voltage      | 300   | [V]   |
| Rated Speed          | 1500  | [rpm] |
| Phase Resistance     | 0.4   | [Ω]   |
| Phase Inductance     | 13    | [mH]  |
| Load Torque          | 3     | [N.m] |
| Moment of Inertia    | 0.004 | [kg.m²] |
| Torque Constant      | 0.4   | [V/(rad/sec)] |
| Damping Constant     | 0.002 | [N.m/(rad/sec)] |

![Fig. 5. Block diagram of sliding mode observer](image)
superior performance of the sliding mode observer rather than employing look-up table and position sensors.

The estimated load torque is illustrated in Fig. 11 (a), and the estimated electromagnetic torque is presented in Fig. 11(b).

Figs. 10(a) and 10(b) depict the identified parameters $\hat{B}$ and $\hat{J}$ which confirm the efficiency of the RLS method.

Fig. 10. Identified parameters, (a) Viscous damping coefficient, (b) moment of inertia

Fig. 9. Back-EMF ($e_q$), (a) Real value, (b) Estimated value

Fig. 8. Back-EMF ($e_d$), (a) Real value, (b) Estimated value
have proven the success of the proposed approach.

VII. CONCLUSION
This paper has proposed an innovative plan to control brushless DC motor drives with no position sensor. In this plan, DTC also has been used due to its advantages. Another algorithm applied here is the RLS, which is used to assess some parameters of the speed observer in order to calculate the rotor speed. To satisfy the need for back-EMF estimation, a sliding mode observer is utilized. The proposed scheme can estimate the speed from standstill to the steady state. Simulation results have proven the success of the proposed approach.
