We present the first direct experimental bound on the total decay width of the top quark, $\Gamma_t$, using 955 pb$^{-1}$ of the Tevatron’s $p\bar{p}$ collisions recorded by the Collider Detector at Fermilab. We identify 253 top-antitop pair candidate events. The distribution of reconstructed top quark mass from these events is fitted to templates representing different values of the top quark width. Using a confidence interval based on likelihood ratio ordering, we extract an upper limit at 95% C.L. of $\Gamma_t < 13.1$ GeV for an assumed top quark mass of 175 GeV/c$^2$.

PACS numbers: 14.65.Ha, 13.85.Qk, 12.15.Ff
Due to its large mass, the top quark has the largest decay width and hence the shortest lifetime of the quarks in the standard model (SM). The total width of the top quark at the leading order is dependent on the top quark mass \( m_t \) and the Fermi coupling constant \( G_F \):

\[
\Gamma_t = G_F m_t^3/\left(8\pi\sqrt{2}\right).
\]

Higher order effects include the introduction of finite \( W \) boson and \( b \) quark masses \( (M_W, m_b) \), non-zero off-diagonal elements of the quark-mixing matrix, and higher order corrections in the strong coupling constant \( \alpha_s \). Neglecting terms of order \( m_b^2/m_t^2 \), \( \alpha_s/M_W^2 \), and \( \alpha_s/\pi M_W^2/m_t^2 \), the width predicted in the SM at next-to-leading-order is:

\[
\Gamma_t = \Gamma_t^0 \left(1 - \frac{M_W^2}{m_t^2}\right)^2 \left(1 + 2\frac{M_W^2}{m_t^2}\right) \left[1 - \frac{2\alpha_s}{3\pi} \left(\frac{2\pi^2}{3} - \frac{5}{2}\right)\right].
\]

The total width of the top quark is calculated to a precision of about 1% in the SM; it is approximately 1.5 GeV for \( m_t = 175 \) GeV/c\(^2\) [12].

A deviation from the SM prediction could indicate a significant contribution from top quark decays to non-SM particles such as \( t \rightarrow bH^+ \) (where \( H^+ \) is the charged Higgs boson in the supersymmetric model), or from rare SM processes such as \( t \rightarrow dW^+ \) and \( t \rightarrow sW^+ \). Although such scenarios have not been observed experimentally [3,4,6,7], a general way to rule out the presence of a large top quark decay rate to non-SM channels, including those with non-detectable final states, is through experimental constraints on \( \Gamma_t \). To date, there have been no direct experimental measurements of the total width of the top quark.

The data set for the analysis presented in this paper is collected by the CDF II detector, a multipurpose particle detector for \( pp \) collisions at \( \sqrt{s} = 1.96 \) TeV at the Fermilab Tevatron. A charged particle tracking system immersed in a magnetic field consists of a silicon microstrip tracker and a drift chamber. Electromagnetic and hadronic calorimeters surround the tracking system and measure particle energies. Drift chambers and scintillators located outside the calorimeters detect muons. The detector is described in detail elsewhere [8].

We employ a cylindrical coordinate system where \( \theta \) and \( \phi \) are the polar and azimuthal angle, respectively, with respect to the proton beam. Transverse energy and momentum are \( E_T = E \sin \theta \) and \( p_T = |p| \sin \theta \), respectively, where \( E \) and \( p \) are energy and momentum. Missing transverse energy, \( E_T \), is defined as the magnitude of the vector \(-\Sigma_i E_T^i \mathbf{n}_i\) where \( E_T^i \) is the magnitude of transverse energy contained in each calorimeter tower \( i \), and \( \mathbf{n}_i \) is the unit vector from the collision point to the tower in the transverse plane.

Top quarks are produced primarily by strong interaction in top-antitop (\( tt \)) pairs at the Tevatron. Top quarks decay almost exclusively to a \( W \) boson and a \( b \) quark through the weak interaction in the SM. We identify candidate \( tt \) events in the “lepton + jets” channel, where one \( W \) boson decays to an electron or a muon, and a neutrino, while the other \( W \) boson decays to a quark-antiquark pair. We select events consistent with this topology, requiring a high-\( p_T \) electron or muon candidate, missing transverse energy denoting the presence of a neutrino, and four jets. Jets are reconstructed using a cone algorithm with radius \( \Delta R = \sqrt{\Delta \eta^2 + \Delta \phi^2} = 0.4 \). At least one jet with \( E_T > 15 \) GeV must be identified as a \( b \) quark candidate through the presence of a displaced vertex within the jet cone arising from the decay of a long-lived bottom hadron (\( b \)-tag). The event selection criteria are listed in Table I. Detailed information on event selection is available elsewhere [9,10].

We divide the candidate events into two exclusive classes: one (1-tag) containing events with one \( b \)-tagged jet among the leading four, and another (2-tag) with two or more such jets. Separating these subsamples results in a more efficient use of statistical information due to their different reconstructed top mass resolution and signal-to-background ratios. Background events are expected primarily from \( W \) production in association with jets (\( W + \) jets), multijet processes where a jet is misidentified as a charged lepton and \( E_T \) results from energy mismeasurement of the jets (non-\( W \)), and small contributions from electroweak backgrounds (EWK) composed of single top quark and diboson (\( WW, WZ, ZZ \)) production. Table II summarizes the expected sample compositions that are obtained by scaling to 955 pb\(^{-1}\) from a previous \( tt \) analysis with 318 pb\(^{-1}\) [11].

After event selection, the analysis proceeds in three steps. First, we reconstruct a top quark mass \( m_t^{\text{reco}} \) from each event using a kinematic fitter. The width of the
require that different ways of assigning the jets to the four quarks, we and b using the four leading jets. We assume that the final Bayesian treatment of systematic uncertainties \cite{12}) to of \(\Gamma\) of reconstructed mass distributions using simulated signal and background distributions that yields an estimator \(\Gamma\). Finally, we use a frequentist prescription (with Bayesian treatment of systematic uncertainties \cite{12}) to determine a 95\% C.L. upper limit on \(\Gamma\) in the physically allowed region.

We perform a \(\chi^2\) minimization to fit the momenta of the \(tt\) decay products and determine \(m_{t_1}^{\text{reco}}\) for each event using the four leading jets. We assume that the final state arises from the decay of a \(tt\) pair into \(W\) bosons and \(b\) quarks. To resolve the ambiguity arising from the different ways of assigning the jets to the four quarks, we require that \(b\)-tagged jets are assigned to \(b\) quarks and select the assignment with the lowest \(\chi^2\). This kinematic fitter is used in other CDF analyses and is described in detail in Ref. \cite{11}. In the \(\chi^2\) fit, both sets of \(W\) decay daughters are constrained to have the invariant mass of the \(W\) boson, and both \(Wb\) states are constrained to have the same mass. Although the top and antitop quark will likely be produced with different masses, we confirmed that there is no significant difference in the sensitivity resulting from the \(m_t = m_{\bar{t}}\) condition even for a large value of \(\Gamma_t\).

To distinguish between different values of \(\Gamma_t\), we compare the \(m_{t_1}^{\text{reco}}\) distribution from our data to a series of samples created using the PYTHIA 6.216 event generator \cite{13} and a full detector simulation. We use samples with \(m_t = 175\) GeV/\(c^2\) and various values of \(\Gamma_t\) between 0.001 GeV and 100 GeV. Although PYTHIA does not fully account for quantum interference with irreducible background diagrams and off-shell effects, for \(\Gamma_t \lesssim 30\) GeV these effects are small, and the existing description is expected to be adequate \cite{14}. \(W + \) jets background events are generated using ALPGEN 1.3 \cite{15}, with parton showering and fragmentation in HERWIG 6.504 \cite{16}. An unbinned extended maximum likelihood fit \cite{17} is performed using parameterized signal and background \(m_{t_1}^{\text{reco}}\) templates. As an example, Fig. [1] shows templates for the signal \(m_{t_1}^{\text{reco}}\) distribution in the 2-tag subsample at three values of \(\Gamma_t\). We parameterize the \(m_{t_1}^{\text{reco}}\) distributions as a function of \(\Gamma_t\). Small shifts in the mean of the templates are induced by the interplay between the top mass Breit-Wigner distribution and the parton distribution functions that preferentially produce events with low quark masses. In the likelihood fit, we constrain the background templates in the 2-tag and 1-tag samples to the levels given in Table [II]. The best fit value \(\Gamma_t^{\text{fit}}\) is the width which maximizes the likelihood.

We allow negative \(\Gamma_t^{\text{fit}}\) values that represent \(m_{t_1}^{\text{reco}}\) distributions narrower than the nominal due to statistical fluctuations. The expected \(m_{t_1}^{\text{reco}}\) distribution for a negative \(\Gamma_t^{\text{fit}}\) is derived from an extrapolation of the parameterization to the unphysical region. The reconstructed top mass distributions from the data and the results of the likelihood fit are shown in Fig. [2]. The data are consistent with the fitted curves with the preferred value of \(\Gamma_t^{\text{fit}} = -4.8\) GeV. For the data sample used in this analysis, we expect to measure a negative \(\Gamma_t^{\text{fit}}\) about 40\% of the time and \(\Gamma_t^{\text{fit}} \lesssim -4.8\) GeV about 25\% of the time if the total width is 1.5 GeV. The limit on the true value of \(\Gamma_t\), however, will be constrained to the physical region.

To set a limit on the true value of \(\Gamma_t\), we employ the Neyman construction \cite{18} to ensure a coverage of at least 95\%. The likelihood-ratio ordering principle due to Feldman and Cousins \cite{19} provides a smooth transition from one-sided to two-sided limits and usually guarantees a non-empty interval. We derive the confidence belts from ensembles of simulated experiments in which signal events are selected from the simulated samples generated with different values of \(\Gamma_t\). The \(\Gamma_t^{\text{fit}}\) distribution from each such ensemble is convoluted with a shape that represents the effects of systematic uncertainties as de-

| Background source | 1-tag | 2-tag |
|-------------------|-------|-------|
| \(W + \) jets     | 21.4 ± 4.9 | 4.6 ± 1.5 |
| non-\(W\)         | 7.0 ± 1.5  | 0.9 ± 0.2  |
| EWK               | 2.8 ± 0.6  | 0.17 ± 0.04 |
| Total background events | 31.2 ± 7.0 | 5.7 ± 1.8 |
| Observed events    | 171 | 82 |

*TABLE II:* The sources and expected numbers of background events, and the number of events observed for the 1-tag and 2-tag event samples in our 955 pb\(^{-1}\) dataset.

We perform a \(\chi^2\) minimization to fit the momenta of the \(tt\) decay products and determine \(m_{t_1}^{\text{reco}}\) for each event using the four leading jets. We assume that the final state arises from the decay of a \(tt\) pair into \(W\) bosons and \(b\) quarks. To resolve the ambiguity arising from the different ways of assigning the jets to the four quarks, we require that \(b\)-tagged jets are assigned to \(b\) quarks and select the assignment with the lowest \(\chi^2\). This kinematic fitter is used in other CDF analyses and is described in detail in Ref. \cite{11}. In the \(\chi^2\) fit, both sets of \(W\) decay daughters are constrained to have the invariant mass of the \(W\) boson, and both \(Wb\) states are constrained to have the same mass. Although the top and antitop quark will likely be produced with different masses, we confirmed that there is no significant difference in the sensitivity resulting from the \(m_t = m_{\bar{t}}\) condition even for a large value of \(\Gamma_t\).

To distinguish between different values of \(\Gamma_t\), we compare the \(m_{t_1}^{\text{reco}}\) distribution from our data to a series of samples created using the PYTHIA 6.216 event generator \cite{13} and a full detector simulation. We use samples with \(m_t = 175\) GeV/\(c^2\) and various values of \(\Gamma_t\) between 0.001 GeV and 100 GeV. Although PYTHIA does not fully account for quantum interference with irreducible background diagrams and off-shell effects, for \(\Gamma_t \lesssim 30\) GeV these effects are small, and the existing description is expected to be adequate \cite{14}. \(W + \) jets background events are generated using ALPGEN 1.3 \cite{15}, with parton showering and fragmentation in HERWIG 6.504 \cite{16}. An unbinned extended maximum likelihood fit \cite{17} is performed using parameterized signal and background \(m_{t_1}^{\text{reco}}\) templates. As an example, Fig. [1] shows templates for the signal \(m_{t_1}^{\text{reco}}\) distribution in the 2-tag subsample at three values of \(\Gamma_t\). We parameterize the \(m_{t_1}^{\text{reco}}\) distributions as a function of \(\Gamma_t\). Small shifts in the mean of the templates are induced by the interplay between the top mass Breit-Wigner distribution and the parton distribution functions that preferentially produce events with low quark masses. In the likelihood fit, we constrain the background templates in the 2-tag and 1-tag samples to the levels given in Table [II]. The best fit value \(\Gamma_t^{\text{fit}}\) is the width which maximizes the likelihood.

We allow negative \(\Gamma_t^{\text{fit}}\) values that represent \(m_{t_1}^{\text{reco}}\) distributions narrower than the nominal due to statistical fluctuations. The expected \(m_{t_1}^{\text{reco}}\) distribution for a negative \(\Gamma_t^{\text{fit}}\) is derived from an extrapolation of the parameterization to the unphysical region. The reconstructed top mass distributions from the data and the results of the likelihood fit are shown in Fig. [2]. The data are consistent with the fitted curves with the preferred value of \(\Gamma_t^{\text{fit}} = -4.8\) GeV. For the data sample used in this analysis, we expect to measure a negative \(\Gamma_t^{\text{fit}}\) about 40\% of the time and \(\Gamma_t^{\text{fit}} \lesssim -4.8\) GeV about 25\% of the time if the total width is 1.5 GeV. The limit on the true value of \(\Gamma_t\), however, will be constrained to the physical region.

To set a limit on the true value of \(\Gamma_t\), we employ the Neyman construction \cite{18} to ensure a coverage of at least 95\%. The likelihood-ratio ordering principle due to Feldman and Cousins \cite{19} provides a smooth transition from one-sided to two-sided limits and usually guarantees a non-empty interval. We derive the confidence belts from ensembles of simulated experiments in which signal events are selected from the simulated samples generated with different values of \(\Gamma_t\). The \(\Gamma_t^{\text{fit}}\) distribution from each such ensemble is convoluted with a shape that represents the effects of systematic uncertainties as de-
signal Monte Carlo events. We also study smaller systematic uncertainties in $\Gamma_{t}^{\text{fit}}$ related to the background $m_{t}^{\text{reco}}$ shape, Monte Carlo statistics, the Monte Carlo generator, the parton distribution functions, and other signal modeling effects [11]. The combined convolution shape, accounting for all systematic uncertainties, has a shift of $-0.4$ GeV and an RMS of $4.6$ GeV. This can be compared to the RMS from statistical effects only: between $6.6$ GeV and $10.1$ GeV for simulated experiment ensembles using $\Gamma_{t}$ of $1.5 - 30$ GeV. Figure 3 shows the 95% confidence belts after including systematic uncertainties. The fitted value from data, $\Gamma_{t}^{\text{fit}} = -4.8$ GeV, corresponds to a limit of $\Gamma_{t} < 13.1$ GeV at 95% C.L.

Our measurement assumes a fixed value for the top quark mass of $175$ GeV$/c^2$. The one-dimensional likelihood is sensitive to this assumption in the same way as described above for jet energy scale uncertainties. In particular, if the top quark mass is consistent with the current world average of $171.2 \pm 2.1$ GeV$/c^2$ [21], the confidence belts would shift to higher $\Gamma_{t}^{\text{fit}}$ values, resulting in an upper limit of $\Gamma_{t}$ lower than what we quoted in this paper.

In summary, using 253 top-antitop pair candidate events we present the first direct experimental upper limit on the total decay width of the top quark, $\Gamma_{t} < 13.1$ GeV at 95% C.L. for $m_{t} = 175$ GeV$/c^2$. This corresponds to a limit on the top quark lifetime of $\tau_{t} > 5 \times 10^{-26}$ s. This measurement is statistically limited and its dominant systematic uncertainties are likely reducible with statistics. The precision of this measurement, therefore, will continue to improve over the course of Run II of the Tevatron.

We thank Torbjörn Sjöstrand, Stephen Mrenna, Peter Skands, Alessandro Ballestrero, and Ezio Maina for discussions related to the Monte Carlo modeling of the top quark lineshape. We thank the Fermilab staff and the technical staffs of the participating institutions for their vital contributions. Sloan Foundation; the Bundesministerium für Bildung und Forschung, Germany; the Korean Science and Engineering Foundation and the Korean Research Foundation; the Science and Technology Facilities Council and the Royal Society, UK; the Institut National de Physique Nucleaire et Physique des Particules/CNRS; the Russian Foundation for Basic Research; the Comisión Interministerial de Ciencia y Tecnología, Spain; the European Community’s Human Potential Programme; the Slovak R&D Agency; and the Academy of Finland.
FIG. 3: The confidence band in $\Gamma_{fit}$ for a 95% C.L. is shown. Results from simulated experiments assuming a 955 pb$^{-1}$ dataset at different values of $\Gamma_t$ are convoluted with a smearing function to account for systematic uncertainties. The fitted value from the data is indicated by an arrow.
