Hyponatremia is Associated with Fluid Imbalance and Adverse Renal Outcome in Chronic Kidney Disease Patients Treated with Diuretics

Lee Moay Lim1,*, Ni-Chin Tsai1,2,*, Ming-Yen Lin1,3, Daw-Yang Hwang1, Hugo You-Hsien Lin1,4, Jia-Jung Lee1, Shang-Jyh Hwang1,3, Chi-Chih Hung1 & Hung-Chun Chen1,3

Chronic kidney disease (CKD) is frequently complicated with hyponatremia, probably because of fluid overload or diuretic usage. Hyponatremia in CKD population is associated with increased mortality, but the effect on renal outcome was unknown. We investigated whether hyponatremia is associated with fluid status and is a prognostic indicator for adverse outcomes in a CKD cohort of 4,766 patients with 1,009 diuretic users. We found that diuretic users had worse clinical outcomes compared with diuretic non-users. Hyponatremia (serum sodium <135 mEq/L) was associated with excessive volume and volume depletion, measured as total body water by bioimpedance analysis, in diuretic users, but not in diuretic non-users. Furthermore, in Cox survival analysis, hyponatremia was associated with an increased risk for renal replacement therapy (hazard ratio, 1.45; 95% CI, 1.13–1.85, P < 0.05) in diuretic users, but not in diuretic non-users (P for interaction <0.05); restricted cubic spline model also showed a similar result. Hyponatremia was not associated with all-cause mortality or cardiovascular event whereas hypernatremia (serum sodium >141 mEq/L) was associated with an increased risk for all-cause mortality. Thus, hyponatremia is an indicator of fluid imbalance and also a prognostic factor for renal replacement therapy in CKD patients treated with diuretics.

Chronic kidney disease (CKD) is frequently complicated with hyponatremia, probably because of fluid overload or diuretic usage. Hyponatremia in CKD population is associated with increased mortality, but the effect on renal outcome was unknown. We investigated whether hyponatremia is associated with fluid status and is a prognostic indicator for adverse outcomes in a CKD cohort of 4,766 patients with 1,009 diuretic users. Thus, hyponatremia is an indicator of fluid imbalance and also a prognostic factor for renal replacement therapy in CKD patients treated with diuretics.
Hyponatremia could be a prognostic indicator in patients with CKD. Thus, the aim of our study was to determine whether diuretic usage and the related hyponatremia are associated with fluid imbalance and are predictive of adverse clinical outcomes, including renal outcomes, in patients with CKD.

**Results**

**Baseline characteristics and clinical outcomes of the diuretic users and diuretic non-users.**

Table 1 showed the baseline characteristics of diuretic users and non-users which comprised of 1,009 and 3,757 respectively. The diuretic users showed higher percentage of CHF, Diabetes mellitus (DM), CVD and severe liver disease (SLD). They exhibited a significantly higher mean blood pressure, urine protein-to-creatinine ratio (UPCR) and HbA1c level ($p < 0.05$). At the same time, lower estimated glomerular filtration rate (eGFR), serum hemoglobin and albumin were observed in diuretic users (Table 1). However, only male diuretic users showed higher total body water (TBW) ($55.5 \pm 8.2\%$ vs $54.0 \pm 5.7\%)$. Diuretic users also showed higher percentage of renal replacement therapy (RRT) and CVD.

**Hyponatremia and total body water in diuretic users.**

Table 3 showed the variables associated with hyponatremia (Na < 135 mEq/L) in diuretic users. To understand whether hyponatremia could be an indicator of fluid status, we measured TBW by using the bioimpedance method in 498 randomly selected diuretic users and performed logistic regression to determine the nonlinear association between serum
Table 2. Baseline characteristics of diuretic users according to serum sodium. Abbreviations: CHF, congestive heart failure; DM, Diabetes mellitus; CVD, cardiovascular disease; SLD, Severe liver disease; BMI, Body mass index; BP, blood pressure; eGFR, estimated glomerular filtration rate; CRP, C-reactive protein; UPCR, Urine protein-to-creatinine ratio; ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; Anti-HTN, anti-hypertensive; OAD, Oral antidiabetic drug. Continuous variables are expressed as mean ± standard deviation or median (inter-quartile range), and categorical variables are expressed as number and percentage. P for trend < 0.05 indicates a significant trend for increasing Na levels.

| Demographics and Medical History | Na (mEq/L) | p for trend |

sodium and TBW. Our results showed that the lowest and highest quartiles of TBW were associated with hyponatremia (Table 3). Age, CVD, HbA1c and BMI also showed positive correlation with hyponatremia but not thiazide diuretics. No association between serum sodium and TBW was noted in diuretic non-users (Supplementary Table 1). CVD, eGFR, albumin, HbA1c and BMI showed positive correlation with hyponatremia in diuretic non-users.

**Association between serum sodium and clinical outcomes in diuretic users.** In diuretic users, after a median follow-up of 1070 days, the RRT event was higher in Na < 135 mEq/L, which was 113 (62.4%) (Table 4). In fully-adjusted competing risk Cox regression model, compared with Na 135–138 mEq/L, Na < 135 mEq/L was associated with an adjusted HR of 1.45 (95% CI, 1.13–1.85; P < 0.05) for RRT, but not associated with all-cause mortality and cardiovascular events (Table 4). Na > 141 mEq/L was associated with a trend of
increased risk for RRT. When compared with Na 138–141 mEq/L, Na >141 mEq/L had an adjusted HR of 1.59 (95% CI, 1.09–2.32; P < 0.05) for all-cause mortality. In analysis of serum sodium and outcomes as restricted cubic splines, we observed that Na <132 mEq/L was associated with a higher risk for RRT (Fig. 1) whereas Na >143 mEq/L was associated with a higher risk for all-cause mortality (Fig. 2).

Association between serum sodium and clinical outcomes in diuretic non-users and interaction between diuretic use and serum sodium. We studied the prognostic effect of sodium in diuretic non-user (Supplement Table 2). The percentage of Na <135 mEq/L in diuretic users was 17.3% similar to that in diuretic users, 17.9%. Na <135 mEq/L was associated with increased risks of RRT, all-cause mortality and cardiovascular events in unadjusted models; however, the result became non-significant after adjustment (Supplement Table 2). In analysis of serum sodium and outcomes as restricted cubic splines, we also did not observe a significant association (Supplement Figures 1, 2 and 3). The interaction between diuretic use and serum sodium for RRT was significant with a p value of 0.017 and 0.038, when serum sodium treated as a categorical variable or a continuous variable, respectively.

Sensitivity test for the association between serum sodium and clinical outcomes. We tested other grouping methods as stated in the method. In diuretic users, compared with Na 135–141 mEq/L, Na >141 mEq/L had an increased risk of RRT and Na >141 mEq/L was associated with a higher risk for all-cause mortality (Table 3). In analysis by restricted cubic spline model with different knots, we also observed that Na <132 mEq/L was associated with increased risk for all-cause mortality (Supplement Figure 4) whereas Na >143 mEq/L was associated with a higher risk for all-cause mortality (Supplement Figure 5). In diuretic non-users, serum sodium treated as a categorical variable (3 groups) or as a continuous variable with different knots showed similar results (data not shown). The interaction between diuretic use and serum sodium for RRT was also significant with a p value of 0.024 and 0.036, when serum sodium treated as a categorical variable or a continuous variable, respectively (data not shown).

Discussion
We investigated the diuretic usage, clinical outcomes, and prognostic effect of serum sodium among patients in a CKD cohort. We found that hyponatremia is associated with imbalance of TBW in diuretic users. In investigating the prognostic effect of diuretic-related hyponatremia, we revealed, for the first time, that serum sodium <135 mEq/L is independently associated with a higher risk for RRT in diuretic users, but not in diuretic non-users. Moreover, we also observed that serum sodium >141 mEq/L is associated with an increased risk for all-cause mortality.

Previous studies on the effects and outcomes of diuretic usage have mainly focused on patients with AKI or edematous diseases other than kidney disease. Using diuretics to treat AKI provides no clear benefits in the recovering of kidney function or preventing mortality other than maintaining urine output. Moreover, diuretic usage by critically ill patients with AKI was associated with an increased risk of death and non-recovery in renal...
Table 4. Associations between serum sodium and outcomes in diuretic users. Adjusted for age, gender, eGFR, diabetes mellitus, cardiovascular disease, mean blood pressure, HbA1c, hemoglobin, albumin, cholesterol, log-transformed urine protein to creatinine ratio, log-transformed C-reactive protein, body mass index, ACEI/ARB, anti-HTN agents, OAD agents, statins, integrated CKD care and causes of renal diseases. *(p < 0.05) indicates a significantly different from reference group.

Figure 2. Association between serum sodium and all-cause mortality by restricted cubic spline model in diuretic users.
function. Observational studies have shown that diuretic usage by patients with heart failure is associated with reduced renal function, the progression of heart failure and increased mortality. Compared with paracentesis, diuretic usage was associated with a higher incidence of renal impairment and other complications in patients with liver cirrhosis and ascites. These data suggest that diuretic usage could be harmful to patients with extreme volume changes.

Clinical trials in patients with hypertension have yielded controversial results regarding the effects of diuretic usage on clinical outcomes. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) reported that thiazide diuretics were not inferior to calcium channel blockers and angiotensin-converting enzyme inhibitors in preventing all-cause mortality and were superior in preventing CVD. The renal outcomes of these drugs did not differ. However, in the Avoiding Cardiovascular Events in Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) study, benazepril plus hydrochlorothiazide, compared with benazepril plusamlodipine, were more strongly associated with hyponatremia and higher risks of the progression of CKD, cardiovascular morbidity, and mortality. These data suggest that thiazide diuretics could be harmful if they cause volume depletion.

Little research has examined the association between diuretic usage and outcomes in CKD comparatively. Diuretics have considerable therapeutic importance in treatment volume overload of CKD patients, but may possess direct nephrotoxicity, particularly tubulointerstitial injury and impaired renal vaso-relaxation. The overuse of diuretics causes volume depletion and subsequently increased sympathetic activity and stimulates the renin-angiotensin-aldosterone system, as evidenced by animal studies. Both local renal effects and systemic neuro-hormonal effects impair renal function. In patients with hypertension and GFR <60 mL/min/1.73 m², thiazide diuretics were not inferior to 2 other drugs in reducing end-stage renal disease in the ALLHAT study, and benazepril plus hydrochlorothiazide were not associated with hypotension or a higher risk of the progression of CKD in the ACCOMPLISH study. No previous studies investigated the impact of loop diuretics in patients with CKD. In our study, we discovered that diuretic users (80% loop diuretics) had worse clinical outcomes. However, the causal relationship between them could not be determined.

In patients with CKD and volume overload, diuretic usage may be a necessary evil in managing volume status. High prevalence of volume overload in CKD patients lead to unavoidable diuretic usage. Volume status could be measured by using the bioimpedance method, which reflects the status of hydration quantitatively. However, this is not routinely used in daily practice. We found hyponatremia under diuretic usage could become a clinical parameter which indicates the increased TBW (increased fluid status despite diuretic use) or decreased TBW (likely because of too much diuretic use). Hyponatremia with increased TBW denotes water and salt retention because of impaired renal excretion and activation of the neuro-hormonal mechanisms. The increased fluid status would increase renal efferent pressure and decrease renal blood flow. Our previous study had shown that fluid overload is associated with worse renal outcome. Conversely, hyponatremia with decreased TBW suggests volume depletion under diuretic usage, which enhances arginine-vasopressin (AVP) and renin-angiotensin secretion. Acute volume depletion is well-known as a cause of acute renal injury and chronic volume depletion could lead to chronic tubulointerstitial injury and CKD. Volume depletion also decreases renal perfusion and increases the susceptibility to analgesics and nephrotoxic agents. Thus, hyponatremia indicates imbalanced volume status and could be associated with renal function progression.

Hyponatremia could also indicate an impaired renal dilution capability in CKD patients. As CKD progresses, renal sodium loss because of impaired tubular reabsorption and osmotic disequilibrium between the luminal fluid and medullary interstitial impair dilution. CKD is also associated with increased AVP secretion and experimental evidence has demonstrated that AVP is critical in initiating and exacerbating renal damage. A sustained stimulation of vasopressin receptors induced intrarenal renin-angiotensin system activation, glomerular hyperfiltration, and hypertrophy, causing proteinuria and glomerulosclerosis. However, our data demonstrated that hyponatremia in diuretic users was associated with lower eGFR but was not associated with adverse clinical outcomes. Besides, thiazide diuretics, which inhibit sodium transport in the distal tubule, could prevent the maximal dilution of urine. But we found no association between hyponatremia and thiazide diuretics in diabetic users. These data suggest that impaired renal dilution capability could not explain the prognostic effect of hyponatremia in diuretic users.

Hyponatremia may also reflect concurrent heart failure, which may impose additive deleterious effects on poor renal outcomes. Fluid overload as indicated by hyponatremia could cause cardiomyocyte elongation and dysfunction during the left ventricle remodeling. Our data demonstrated that hyponatremia was associated with cardiovascular disease in patients with CKD. Hoorn et al. demonstrated that hyponatremia predicts declining creatinine clearance in patients with severe heart failure. The concourse of hyponatremia and renal dysfunction has been shown to be associated with heart and liver failure. Thus, cardiorenal syndrome can cause a vicious cycle in which deteriorating heart function accelerates the reduction in kidney function via the neurohormonal pathways.

Hyponatremia is an independent prognostic factor for morbidity and mortality in heart failure and maintenance hemodialysis. Kovesdy et al. concluded that lower serum sodium (<135.9 mEq/L) and higher serum sodium (>145 mEq/L) were associated with higher mortality in a large cohort of patients with non-dialysis-dependent CKD. In our CKD cohort, the lack of association between hyponatremia and mortality could be attributed to the fact that renal replacement therapy could resolve the fluid overload eventually in patients with advanced CKD. Our data also reconfirmed the association between hyponatremia and mortality in CKD patients. Hyponatremia (serum sodium >145 mEq/L) was much less than hyponatremia (serum sodium <135 mEq/L), 3% vs 17%. Patients with hyponatremia could be associated with acute complications and death, rather than RRT.
Our study had several limitations. First, as an observational cohort, our ability to elucidate definite causal links was limited. Second, total body water measured by bioelectrical impedance analysis was not equal to extracellular fluid, though we had found a good correlation. Third, CV events were recorded in only one hospital, which might have caused an underestimation. Fourth, variations in serum sodium levels caused by daily intake, nutritional status, and medication use during the follow-up period could have confounded the results. However, our purpose was to apply serum sodium as a prognostic factor, not a causal factor. Fifth, the smaller sample size of the 2 extreme serum sodium levels and relatively short follow-up duration could have resulted in lower statistical power, which might account for the weak association with mortality and CV events and the inability to differentiate the effects of loop and thiazide diuretics.

In conclusion, diuretic users have adverse clinical outcomes in CKD population. Hyponatremia is associated with imbalanced TBW and is a prognostic indicator for RRT in diuretic users, but not in diuretic non-users. Hyponatremia was not associated with all-cause mortality or cardiovascular event whereas hypernatremia was associated with an increased risk for all-cause mortality. Therefore, the serum sodium levels of patients with CKD who are being treated with diuretics should be routinely evaluated. Additionally, interventions other than diuretics aimed at achieving optimal fluid status should be considered. Whether the mechanism behind hyponatremia is diuretic-induced direct renal injury or neuro-hormonal activation requires further study.

Methods

Participants and Measurement. Between November 11, 2002, and June 30, 2009, 5,047 patients who were screened through an integrated CKD care program at 2 affiliated hospitals of Kaohsiung Medical University in Southern Taiwan were included in the CKD cohort and followed until July 31, 2010. Integrated CKD care program Kaohsiung for delaying dialysis (ICKD) study was designed as a prospective cohort study to investigate the impact of an integrated CKD care program on clinical outcomes in patients with CKD stages 1–5 not on dialysis. CKD was staged according to K/DOQI definitions and the estimated glomerular filtration rate (eGFR) was calculated using the equation of the 4-variable Modification of Diet in Renal Disease (MDRD) Study. A total of 123 patients who were lost to follow-up within 3 months and 158 patients with incomplete medication information were excluded. Of the patients included, 3,659 were treated as part of the integrated care program and 1,107 received regular care. A total of 4,766 patients with CKD between stages 1 and 5 were eligible for this study. The study protocol was approved by the Institutional Review Board of Kaohsiung Medical University Hospital (KMUH-IRB-990198). Written informed consent was obtained from patients and all clinical investigations were conducted according to the principles expressed in the Declaration of Helsinki.

Baseline variables included demographic features, medical history, examination findings, laboratory data, and medication history. The demographic features were the baseline records when patients enrolled in the CKD care program. The medical history was obtained by reviewing doctor charts. DM and hypertension were defined according to clinical diagnoses and prescribed medications. CVD was defined as a clinical diagnosis of heart failure, acute or chronic ischemic heart disease, or cerebrovascular disease. Diuretic use was defined as loop diuretics exceeding equivalent furosemide 39 mg per day or thiazide diuretics exceeding equivalent trichlormethiazide 3.9 mg per day for more than half of the observation period. Other medication use was also defined as treatment for more than half of the observation period. To prevent variability, electrolytes including serum sodium were collected 3 months before and after enrollment and were averaged. To study the association of clinical outcomes with 2 ends of sodium level, patients were divided into 4 groups according to serum sodium levels, with cut-off values of 135 mEq/L, 138 mEq/L, and 141 mEq/L equal to mean −1 standard deviation (SD), mean, and mean +1 SD, respectively. We also examined serum sodium as a continuous predictor using restricted cubic spline analysis.

Bioelectrical impedance analysis measures the change in impedance of electrical signals, which travel more rapidly through water and lean body mass than through fat body mass. The device used in this study was the InBody 230 (Biospace Co Ltd, Korea), which uses 2 frequencies (20k and 100kHz). Our preliminary data demonstrated that the first and fourth quartiles of TBW (expressed as % of body weight) were associated with adverse clinical outcomes. Accordingly, we defined decreased TBW as the first quartile (<25%) and increased TBW as the fourth quartile (>75%).

Outcomes. Three outcomes were assessed: all-cause mortality, renal replacement therapy (RRT), and cardiovascular events. Survival status and cause of death were ascertained in a death certificate review by using charts and the National Death Index. Cardiovascular events were defined as the development of acute coronary syndrome or acute stroke, hospitalization for peripheral arterial occlusion disease or congestive heart failure, and death by these causes. The development of cardiovascular events was ascertained by reviewing charts. RRT was defined as the initiation of hemodialysis, peritoneal dialysis, or renal transplantation and was ascertained by reviewing charts and catastrophic illness certificate.

Statistical Analysis. The baseline characteristics of all patients are expressed as percentages for categorical data, in mean ± SD for continuous variables with approximately normal distribution, and median and interquartile ranges for continuous variables with skewed distribution. The association between hyponatremia (Na <135 mEq/L) and clinical variables including TBW in diuretic users was evaluated using logistic regression analysis. Competing risk Cox proportional hazard analysis was used to assess the relationship between serum sodium and clinical outcomes. The covariates were selected according to previous studies and our past publications, and the continuous variables with skewed distributions were log-transformed to obtain normal distributions. The adjusted covariates included age, gender, estimated glomerular filtration rate (eGFR), DM, cardiovascular disease, mean blood pressure, glycated hemoglobin, hemoglobin, albumin, cholesterol, urine protein-to-creatinine ratio, C-reactive protein, body mass index, angiotensin-converting enzyme inhibitor/angiotensin II receptor blocker,
Figure 3. Association between serum sodium and cardiovascular event by restricted cubic spline model in diuretic users.

anti-hypertensive agents, oral anti-diabetic drugs, statins, integrated CKD care and causes of renal diseases\(^5\). Serum sodium was treated as a categorical variable with the cut-off at 135, 138, and 141 mEq/L (the 16.6\(^{th}\), 50\(^{th}\), and 83.3\(^{th}\) percentile) in Table 4 and as a categorical variable with the cut-off at 135 and 141 mEq/L (the 16.6\(^{th}\) and 83.3\(^{th}\) percentile) in Supplement Table 3. Serum sodium was treated as a continuous variable with 5 knots at 130, 135, 138, 141, and 142 (the 5\(^{th}\), 16.6\(^{th}\), 50\(^{th}\), and 83.3\(^{th}\) and 95\(^{th}\) percentile) in Figs 1, 2 and 3 and Supplement Figures 1, 2 and 3 and as a continuous variable with 5 default knots at 130, 136, 138, and 141 (the 5\(^{th}\), 13.6\(^{th}\), 50\(^{th}\), and 83.3\(^{th}\) percentile) in Supplement Figures 4–6. 

Serum sodium was treated as a categorical variable with the cut-off at 135, 138, and 141 mEq/L (the 16.6\(^{th}\), 50\(^{th}\), and 83.3\(^{th}\) percentile) in Table 4 and as a categorical variable with the cut-off at 135 and 141 mEq/L (the 16.6\(^{th}\) and 83.3\(^{th}\) percentile) in Supplement Figures 4–6.
