Abstract

Background: We performed the retrospective cohort study to compare the acetabular cup orientation, including anteversion angle (AA) and inclination angle (IA), of dominant hand side and non-dominant hand side after primary total hip arthroplasty (THA) by right-handed orthopedic surgeons.
Methods: Between January 2018 and December 2018, 290 patients who aged below 60 years and underwent primary THA were retrospective screened. Patients who had hemiarthroplasty, previous hip surgery, ankylosing spondylitis, developmental dysplasia of hip (DDH, Crowe type-III and type-IV), severe comorbidity, missing information, inferior quality radiographs were excluded. According to the surgery side, all patients were divided into left group and right group. Postoperative plain radiographs were analyzed to compare the AA and IA between left and right side. Univariate and stepwise multivariable linear regression to control included confounding factors. Stratified analysis was performed to identify whether the operation approach can affect the result, including anterolateral (ALA) and posterolateral approach (PLA).

Results: The mean AA was 17.7° (range 6.0° to 30.0°) and 21.0° (range 9.5° to 35.0°) for the left and right side respectively. The mean difference was 3.28° (95% CI: 1.92 – 4.64; P<0.001). The mean IA was 41.1° (range 24.0° to 59.0°) and 40.1° (range 20.5° to 56.0°) for the left and right side respectively (P=0.314). 113 patients' AA within the “safe zone” in the left (93.4 %), while the right was 93 patients (82.3 %) (P=0.009). 95 patients' IA within the “safe zone” in the left (78.5 %), while the right was 97 patients (85.8 %) (P=0.144). The IA of ALA group was smaller than PLA group in both sides. The mean difference was 3.98° (95% CI: 1.22 - 6.74; P=0.005).

Conclusions: We concluded that AA in left side may be more accurate than right side after primary THA by right-handed surgeons. The IA was no difference between the two sides, while it was smaller in ALA than in PLA. The results are still needed to be verified in future.

Keywords: Total hip arthroplasty; Handedness; Surgery side; Anteversion angle; Inclination angle; Safe zone

Background
Modern total hip arthroplasty (THA) is the most effective method to relieve pain and disability due to a series of end-stage hip disease [1]. The principle causal indications for THA are osteoarthritis (OA, 90%), femoral neck fracture (5%), avascular necrosis (AVN, 2%), developmental dysplasia of hip (DDH, 2%) and inflammatory arthritis (1%) [2]. Accurate acetabular cup position, including anteversion angle (AA) and inclination angle (IA), is critical in THA, as misalignment leads to a higher incidence of dislocation, polyethylene wear, osteolysis, or irritation of the iliopsoas tendon [3-6].

Handedness is defined as the more skillful and flexible of using one hand than the other [7]. The influence of surgeon handedness on surgical procedure and clinical outcomes has been reported previously, especially in general surgery [8], dentistry [9] and urology [10]. Bones are symmetrically distributed in humans, so the surgeons' handedness may have a greater impact on orthopedic surgery than on non-orthopedic surgery [11]. Standing on the right side of the patients during right THA will allow the right-handed surgeon to ream and implant acetabular component comfortably and conveniently. However, it becomes inconvenient when performing the left THA. Up to now, there are extremely limited articles reported the surgeon handedness in orthopedic surgery, especially in primary THA. So, the influence of surgeon handedness on acetabular cup orientation remains unclear.

Therefore, we performed this retrospective cohort study to compare the difference of left and right side primary THA by right-handed surgeon from two aspects: (1) is there any difference between the two sides? (2) which is more accurate?

**Methods**

**Patients**
The study was performed in our hospital between January 2018 and December 2018. 290 patients who aged below 60 years and underwent primary THA were retrospectively screened. Patients who had hemiarthroplasty (7, 2.4%), previous hip surgery (13, 4.5%), ankylosing spondylitis (5, 1.7%), DDH (Crowe type-III and type-IV) (6, 2.1%), severe comorbidity (8, 2.8%), missing information (10, 3.4%), inferior quality radiographs (7, 2.4%) were excluded. Finally, there were 234 patients included (Fig. 1).

Fig. 1. Flowchart that illustrates patient inclusion and exclusion. THA, total hip arthroplasty; DDH, developmental dysplasia of hip; N, number.
All surgeries were performed by orthopedic surgeons with more than 20 years of experience, which made the results reliable. The study was approved by the institutional ethics committee at our institution.

Variables

We conducted the retrospective analysis of all patients' medical records. The data were extracted independently by two researchers. Any difference would be negotiated by a third party. We identified outcomes reported in the previous studies. Radiographic outcomes including AA, IA. Basic demographic information including gender, age, height, weight, body mass index (BMI), diagnosis, operation approach and American Society of Anesthesiologists (ASA).

Postoperative plain radiographs were conducted in anterior-posterior position (AP) of the operation side routinely, which were recorded and evaluated in Picture Archiving and Communication System (PACS). The measurements were made by two researchers independently using a standardized protocol. Only bilateral obturator foramina equally sized would be accepted. The intraclass correlation coefficient (ICC) was calculated to measure the inter-observer reliability for AA and IA. IA is defined as the angle between the long acetabular axis and the horizontal plane and can be directly measured from plain radiographs [12] (Fig. 2). AA is defined as the angle formed by the bottom of the radiographic plate showing the posterior plane of the condyles and the cup opening [12]. The measurement of AA in the AP position of plain radiographs was described in the literature [13] and was shown in the Fig. 2. The values from $30^\circ$ to $50^\circ$ of IA and $5^\circ$ to $25^\circ$ of AA were considered as the "safe zone", according to Lewinnek's definition [5].

Statistical analysis

All statistical analysis was performed by SPSS (IBM version 25.0, Chicago, USA).
Continuous variables were described by mean ± standard deviation (SD), and categorical variables were described by number and percentage. For continuous variables, Kolmogorov-Smirnov test was applied for normal distribution while Mann-Whitney U test for non-normal distribution. Chi-square test and Fisher’s exact test were applied to test categorical variables. Baseline variables considered clinically relevant or univariate in relation to outcomes were included in the multiple linear regression model. Considering the number of events available, the included variables were carefully selected to ensure parsimony of the final model. All statistics were 2-tailed, \( p < 0.05 \) were considered statistical significance, \( p < 0.001 \) were considered dramatically statistical significance [14]. Scatter plots of the variables were graphically presented. Stratified analysis was performed according to different operation approach, including anterolateral (ALA) and posterolateral approach (PLA). ICC was measured and estimated using the grouping recommended by Landis and Koch [15]. A score between 0.61 and 0.8 indicated substantial content, while a score
higher than 0.81 indicated near-perfect agreements content.

**Results**

There were 234 patients (109 female and 125 male) fulfilled the inclusion criteria and were recruited for the final analysis. According to the operation side, they were grouped into the left (N=121) and the right (N=113). Among all of the enrolled participations, the mean age was 44.35±11.32 (22-60) years, the mean BMI was 22.77±3.36 (14.5-35.2) kg/m².

Pre-operative baseline characteristics were collected and analyzed. Reasons for THA were: degeneration (N=34), rheumatoid arthritis (RA, N=13), fracture (N=26), AVN (N=107) and DDH (N=54). There was no statistical significance among all of the baseline variables: gender, age, BMI, diagnosis, ASA and operation approach (Table 1). The mean AA was 17.7° (range 6.0° to 30.0°) and 21.0° (range 9.5° to 35.0°) for the left and right side respectively. The mean difference was 3.28° (95% CI: 1.92 – 4.64; t=-4.741, P<0.001) (Table 2). The mean IA was 41.1° (range 24.0° to 59.0°) and 40.1° (range 20.5° to 56.0°) for the left and right side respectively. There was no statistical significance in AA between the two sides (P=0.314). There were two outliers in the right side (137,138; Fig.3A) After removing the two outliers, there were still no statistical significance in AA between the two sides (P=0.502) (Fig.3B). The IA of ALA group was smaller than PLA group in both sides (P=0.005). The mean difference was 3.98° (95% CI: 1.22 - 6.74; t=-2.840, P=0.005) (Table 3). Scatter plots of AA and IA between the two sides were graphically presented in Fig. 4.

There were 113 patients' AA within the “safe zone” in the left group (93.4 %), while the right was 93 patients (82.3 %). It was statistical significance (P=0.009). There were 95 patients' IA within the “safe zone” in the left group (78.5 %), while the right was 97 patients (85.8 %). It was no statistical significance (P=0.144) (Table 4). There was no difference in AA (P=0.165) and IA (P=0.342)
between the two sides after primary THA by ALA (Table 5). The AA was smaller in the left side
than in the right side after primary THA by PLA (mean difference=3.25°, 95% CI: 1.85 – 4.65; t=-
4.572, P<0.001), while the IA was no difference (P=0.393) (Table 6). Analysis of inter-observer
correlation coefficients for AA (ICC 0.814, P<0.001), and IA (ICC 0.906, P<0.001) were excellent.

Discussion
We performed the current study to compare the difference of AA and IA in left and right side
primary THA by right-handed orthopedic surgeons. Our results were different with Song's [16].
Song et al. conducted a study to investigate the difference of AA and IA in bilateral THA by right-
handed surgeons using PLA. They found that the mean AA was 25.28° in left side and 22.01° in
right side, which were larger than us (left 17.87°, right 21.12°) (Table 6). However, the mean IA
was smaller than us (left 37.50° vs 41.59°; right 38.59° vs 40.65°) (Table 6). Take Lewinnek’s
opinion [5] as standard, 52% of AA and 87% of IA of left side was within the “safe zone”, while
71% of AA and 88% of IA of right side was within the “safe zone”. Both of the percentage of AA and IA within “safe zone” were smaller than us. They thought that the placement of cup in dominant hand side was more accurate than in the non-dominant hand side, which was contrary to us. In Kong's study [17], the AA in left side was 22.44°, which was smaller than right side 24.77°. In Pennington et al.'s study [18], they found that the difference of AA was 3° between the dominant and non-dominant side of surgeons, which was a little smaller than our study.

Combined with previous studies, we could recognize that surgeon handedness may be have an effect on AA. And we could assume that the AA in non-dominant hand side may be smaller than dominant hand side, but it remains unclear which is much better. Several studies [19-21] had reported that AA in THA was a key factor which was related to hip component dislocation. The reason why handedness has an effect on orthopedic surgery was not unclear. We assumed that the standing position may directly affects the accuracy of spatial positioning, and the unaccustomed perspective would further lead to visual errors. In addition, the left and right hand performs completely different tasks during the whole surgery. Therefore, when dominant hand or non-dominant hand dominates a surgical procedure, there are difference in AA.

Operation approach has been discussed affecting the cup orientation [22], so we performed a stratified analysis. After stratified analysis, the AA in the left side was smaller than right side by PLA (mean difference=3.25°, 95% CI: 1.85 – 4.65; t=-4.572, P<0.001), while was no difference by ALA (P=0.165). According to the mean difference (3.35°), we suspected that it may be due to the small sample size in ALA group. Whether in left side or right side, the IA was no statistical difference both in ALA group (P=0.342) and PLA group (P=0.393). Combined with the results discussed above, we can find that the AA was affected by handedness of orthopedic surgeon and left
The side was smaller than right side by right-handed surgeon. The results were unrelated to operation approach. However, the question “which is more accurate?” is still under debating.

The concept of “safe zone” has to be a matter of recent controversy [20, 23]. Some researchers [19, 24-26] have questioned whether the historical concept of “safe zone” has clinical significance. Historical “safe zone” did not take into account individual patients' morphology that might alter component positions, such as changes in pelvic tilt, which has been proved to alter the position of acetabular cup. Danoff et al. [26] suggested that AA should be adjusted to start from 10° to reduce the risk of dislocation. Widmer et al. [27] thought that AA was set at 10-30° can effectively prevent femoral neck impingement. Callanan et al. [28] renewed the “safe zone” and found that it can’t reduce the rate of dislocation. Although the component position has been identified to play a role in hip stability and risk of postoperative dislocation, the evidence for “safe zone” of component position is limited. This may be due to the difference between the surgical approach, methods of measuring and limitation in statistical power [29, 30].

There are several limitations in the study. (1) The study only included right-handed surgeons, and the results in this study may be biased by individual surgeons rather than the general phenomenon. To reduce the inherent bias, the left-handed surgeons should be included in the future. (2) As a retrospective study, the effects of confounders cannot be completely excluded. However, the current study compared the basic characteristics of the two groups, which were likely affect the results, and all of the included variables were consistent. (3) The surgeries were conducted by two orthopedic surgeons. However, both the two surgeons had more than 20-year operating experience and can perform at least 250 surgeries per year, so it can be considered that the two surgeons were consistent in terms of surgical ability. (4) The study used the 2-D radiographic imaging, and the measurements
may be affected by pelvic tilt and rotation. But only bilateral obturator foramina equally sized accepted, which can be considered to be controlled [31]. Although computerized tomography (CT) is more accurate than plain radiograph, Lu et al. [32] and Nho et al. [33] reported that the results measured by plain radiograph were basically consistent with those measured by CT. Although the study concluded that AA was smaller in left side than right side, the postoperative complications, quality of life, and the rate of revision were still unknown.

In a word, surgeon handedness affecting AA after primary THA was proved. However, which is more accurate in placing cup orientation, dominant hand side or non-dominant hand side, remains uncertain. This problem is closely related to the surgeon’s procedure during primary THA. It is still need large sample studies, including left and right-handed surgeons, to solve this problem in the future.

Conclusion

From the study, we concluded that AA in left side may be more accurate than right side after primary THA by right-handed surgeons. The IA was no difference between the two sides, while it was smaller in ALA than in PLA. The results are still needed to be verified in future.

Abbreviations: THA, total hip arthroplasty; N, number; SD, standard deviation; BMI, body mass index; RA, rheumatoid arthritis; AVN, aseptic vascular necrosis; DDH, developmental dysplasia of the hip; ASA, American Society of Anesthesiologists; ALA, anterolateral approach; PLA, posterolateral approach.

#, p<0.05, statistical significance;
*, Fracture included femoral neck fracture and intertrochanteric fracture, but there was no significant displacement;
**, DDH only included Crowe type-I and type-II.

Table 2
Univariate and stepwise multivariable linear regression of AA after THA (N=234)
Table 3

Univariate and stepwise multivariable linear regression of IA after THA (N=234)

| Variables  | Categories | Univariate analysis | Multivariate analysis |
|------------|------------|---------------------|----------------------|
|            |            | p Value | 95%CI    | B^a | p Value | 95% CI |

Abbreviations: IA, inclination angle; THA, total hip arthroplasty; N, number; CI, confidence interval; BMI, body mass index; RA, rheumatoid arthritis; AVN, aseptic vascular necrosis; DDH, developmental dysplasia of the hip; ASA, American Society of Anesthesiologists; ALA, anterolateral approach; PLA, posterolateral approach. a, Unstandardized Coefficients Beta;
b, mean±SD; SD, standard deviation;

*, Fracture included femoral neck fracture and intertrochanteric fracture, but there was no significant
displacement;

**, p<0.05, statistical significance;

&, DDH only included Crowe type-I and type-II.

Table 4
Analysis the proportion of AA and IA in the “safe zone” between left and right side (N=234)

| Variables | Categories | left (N=121) | right (N=113) | p Value* |
|-----------|------------|--------------|---------------|----------|
|           |            | Count | Description | Count | Description |            |
| AA (°)    | Safe       | 113   | 93.4%       | 93    | 82.3%       | 0.009     |
|           | Non-safe   | 8     | 6.6%        | 20    | 17.7%       |           |
| IA (°)    | Safe       | 95    | 78.5%       | 97    | 85.8%       | 0.144     |
|           | Non-safe   | 26    | 21.5%       | 16    | 14.2%       |           |

Abbreviations: AA, anteversion angle; IA, inclination angle; N, number.

#, p<0.05, statistical significance.
Fig. 3. Box plot of inclination angle in both sides. (A) There are two outliers in the right side. (B) Remove the two outliers in the right side. No significant difference between A and B.
Fig. 4. (A) Scatterplot of AA and IA of left side after primary THA. (B) Scatterplot of AA and IA of right side after primary THA. THA, total hip arthroplasty.
