Decision Fusion with Unknown Sensor Detection Probability

D. Ciuonzo, Student Member, IEEE, and P. Salvo Rossi, Senior Member, IEEE

Abstract—In this correspondence we study the problem of channel-aware decision fusion when the sensor detection probability is not known at the decision fusion center. Several alternatives proposed in the literature are compared and new fusion rules (namely “ideal sensors” and “locally-optimum detection”) are proposed, showing attractive performance and linear complexity. Simulations are provided to compare the performance of the aforementioned rules.

Index Terms—Decentralized detection, decision fusion, locally-optimum detection (LOD), wireless sensor networks (WSNs).

I. INTRODUCTION

DECIson fusion (DF) in wireless sensor networks (WSNs) attracted huge interest by the scientific community [1]. In some particular cases, assuming that the sensor probability of detection is higher than the corresponding false-alarm, the uniformly most powerful test is independent on the local sensor probabilities [2] and thus their knowledge is not needed. However, it is typically assumed that the sensor performance is known at the DF center (DFC) [3], [4], [5]. Indeed in the general case sensor performance is required in order to implement the optimal fusion rule, namely the likelihood ratio test (LRT). Unluckily, while the sensor false-alarm can be obtained (since it depends on the local threshold value and the sensing noise distribution), the detection probability is generally difficult to acquire, as it depends on the features of the (unknown) event being observed.

There are two common approaches tackling the aforementioned problem: (i) employing (sub-optimal) rules which neglect the whole sensor performance, such as the “diversity” statistics proposed in [3], [4], [6]; (ii) assuming the knowledge of the local false alarm probabilities and considering the detection probability as an unknown (deterministic) parameter, thus determining a composite hypothesis test [1]. A first remarkable study in the latter direction is found in [2] where a fusion rule, obtained along the same lines of a generalized LRT (GLRT) derivation, has been proposed and shown to have promising results, i.e., being an affine statistic and outperforming the GLRT itself in the considered scenarios.

Unluckily, to the best of our knowledge the two approaches have not been compared yet, and thus it is not immediate whether the sole knowledge of the sensors false alarm probabilities is a potential benefit in the design of efficient fusion rules. Also, another (possibly) useful information is that the sensor detection probability is typically higher than the corresponding false alarm probability (since each “informative” receiver operating characteristic always outperforms an unbiased coin). We will show that jointly exploiting both information can produce performance gains.

In this letter we study channel-aware DF when the false-alarm probability of the generic sensor is known, while the detection probability is unknown. First, we perform (to best of our knowledge, for the first time) a detailed comparison of existing fusion alternatives, not requiring knowledge of sensor detection probability, based on the approaches (i) (i.e. the counting rule [1]) and (ii) (i.e. the rule proposed in [7], denoted here as “Wi rule”). The comparison is strengthened by a theoretical analysis in the case of a large number of sensors, based on deflection measures [8]. Also, we derive two novel rules, based on “ideal sensors” assumption (approach (i)) [3], [4], [9] and locally-optimum detection (approach (ii)) [10]. For all the considered rules high/low signal-to-noise ratio (SNR) optimality properties are established in a scenario with identical sensors and a discussion on complexity and required system knowledge is reported. Finally, the case of non-identical sensors is considered.

The paper is organized as follows: Sec. II introduces the model; in Sec. III we derive and study the fusion rules, while in Sec. IV we generalize the analysis to the case of non-identical sensors; in Sec. V we compare the presented rules and confirm the theoretical findings through simulations; finally in Sec. VI we draw some conclusions; proofs are confined to the Appendix.

II. SYSTEM MODEL

The model is described as follows [2]. We consider a decentralized binary hypothesis test, where $K$ sensors are used to discriminate between the hypotheses of the set $\mathcal{H} = \{H_0, H_1\}$, representing the absence ($H_0$) or the presence ($H_1$) of a specific phenomenon of interest. The a priori probability of $H_1 \in \mathcal{H}$ is denoted $P(H_1)$. The $k$th sensor, $k \in K \triangleq \{1, 2, \ldots, K\}$, takes a binary decision $d_k \in \mathcal{H}$ about the phenomenon on the basis of its own measurements, which is then mapped to a symbol $b_k \in \{0, 1\}$; without loss of generality (w.l.o.g.) we assume that $d_k = H_1 \Rightarrow b_k = i$, $i \in \{0, 1\}$.

The quality of the $k$th sensor decisions is characterized by the conditional probabilities $P(b_k | H_j)$: we denote $P_{b_{1}} \triangleq P(b_{1} = 1|H_{1})$ and $P_{b_{1}} \triangleq P(b_{1} = 1|H_{0})$ the probabilities of detection and false alarm of the $k$th sensor, respectively. Initially, we assume conditionally independent and identically distributed (i.i.d.) decisions; this restriction will be relaxed in Sec. IV. Also we assume $P_{D} > P_{F}$, because of the informativeness of the decision at each sensor. Differently from [3], we assume that $P_{F}$ is known at the DFC, but on the other hand that the true $P_{D}$ is unknown, as studied in [2].

The $k$th sensor communicates to the DFC over a dedicated binary symmetric channel (BSC) and the DFC observes a noisy binary-valued signal $y_k$, that is $y_k = b_k$ with probability $(1 - P_{e,k})$ and $y_k = (1 - b_k)$ with probability $P_{e,k}$, which we collect as $Y \triangleq \begin{bmatrix} y_1 & \cdots & y_K \end{bmatrix}$. Here $P_{e,k}$ denotes the bit-error probability (BEP) of the $k$th link [2]. The BSC model arises when separation between sensing and communication layers is performed in the design phase (namely a “decode-then-fuse” approach [6]).

2 Notation - Lower-case bold letters denote vectors, with $a_{n}$ being the $n$th element of $a$; $\|a\|_p$ denotes the $p$-norm of $a$; upper-case calligraphic letters, e.g., $\mathcal{A}$, denote finite sets; $\mathbb{E}\{\cdot\}$, $\mathbb{V}\{\cdot\}$ and $\{\cdot\}$ denote expectation, variance and transpsose, respectively; $\hat{p}(\cdot)$ and $\hat{p}(\cdot)$ are used to denote probability mass functions (pmf) and probability density functions (pdf), respectively, while $P(\cdot)$ and $p(\cdot)$ their corresponding conditional counterparts; $\mathcal{N}(\mu, \sigma^2)$ denotes a proper complex-valued Gaussian pdf with mean $\mu$ and variance $\sigma^2$, while $Q(\cdot)$ is the complementary cumulative distribution function of a standard normal random variable; $U(a, b)$ denotes a uniform pdf with support $[a, b]$; finally the symbol $\sim$ means “distributed as”.

3 Throughout this letter we make the reasonable assumption $P_{e,k} \leq \frac{1}{2}$.

Manuscript received Oct. 23, 2013; revised Nov. 31, 2013.

This work has been partially supported by the ERCIM within the Alain Bensoussan fellowship programme and by the Faculty of Information Technology, Mathematics and Electrical Engineering of the Norwegian University of Science and Technology, Trondheim, Norway, within the project CAMOS. The authors are with the Dept. Industrial & Information Engineering, Second University of Naples, Aversa (CE), Italy (e-mail: {domenico.ciuonzo, salvorossi}@ieee.org).

In the latter case it is assumed that the sensor detection probability is the same for all the sensors employed (i.e. a homogeneous scenario).
The pmf of $y$ is the same under both $\mathcal{H}_0$ and $\mathcal{H}_1$, except that the value of the unknown parameter $P_i \triangleq P(b_i = 1|\mathcal{H})$ is different. After denoting the pmf with $P(y; P_1)$ the test is summarized as:

$$\mathcal{H}_0 : P_1 = P_F; \quad \mathcal{H}_1 : P_1 > P_F;$$

which is recognized as a one-sided (composite) test [11].

III. Fusion Rules

The final decision at the DFC is performed as a test comparing a signal-dependent fusion rule $\Lambda(y)$ and a fixed threshold $\gamma$:

$$\Lambda(y) \geq \gamma$$

where $\hat{H}$ denotes the estimated hypothesis. Hereinafter we propose different fusion rules for the considered problem.

(Clarivoyant) LRT - in this case we assume that also $P_D$ is known at the DFC. The explicit expression of the LRT is given by

$$\Lambda_{\text{LRT}} \triangleq \ln \left( \frac{P(y; P_1 = P_D)}{P(y; P_1 = P_F)} \right) = \sum_{k=1}^{K} \ln \left( \frac{P(y_k; P_1 = P_D)}{P(y_k; P_1 = P_F)} \right)$$

$$= \sum_{k=1}^{K} \left( y_k \ln \left( \frac{\alpha_k(P_0)}{\alpha_k(P_1)} \right) + (1 - y_k) \ln \left( \frac{\beta_k(P_D)}{\beta_k(P_F)} \right) \right)$$

where $\alpha_k(P_1) \triangleq P(y_k = 1; P_1) = ((1 - 2 P_{e,k}) \cdot P_1 + P_{e,k})$ and $\beta_k(P_1) \triangleq P(y_k = 0; P_1) = (1 - \alpha_k(P_1))$. It is apparent that Eq. (3) should not be intended as a realistic element of comparison, but rather as an optimistic upper bound on the achievable performance (since it makes use of both $P_D$ and $P_F$). Differently, in this letter it is assumed that $P_{e,k}$ can be easily obtained, as in [12].

Ideal sensors (IS) rule - we obtain this rule by assuming that the sensing phase works ideally, that is $(P_D, P_F) = (1, 0)$. This simplifying assumption is exploited in Eq. (4), thus leading to:

$$\Lambda_{\text{IS}} \triangleq \sum_{k=1}^{K} (2 y_k - 1) \ln \left( \frac{1 - P_{e,k}}{P_{e,k}} \right).$$

(4)

The assumption behind Eq. (4) is not new: indeed it was considered in [3], [4], [9] to derive sub-optimal rules (i.e. the maximum ratio and the equal gain combiners) under different communication models.

Locally-optimum detection (LOD) rule - the one-sided nature of the test considered allows to pursue a LOD-based approach, whose implicit expression is given by [10], [11] chap. 6.

$$\Lambda_{\text{LOD}} \triangleq \frac{\partial \ln [P(y; P_1)]}{\partial P_1}\bigg|_{P_1 = P_F} \times \left( I(P_F) \right)^{-1},$$

where $I(P_1)$ represents the Fisher information (FI), that is:

$$I(P_1) \triangleq \mathbb{E} \left\{ \left( \frac{\partial \ln [P(y; P_1)]}{\partial P_1} \right)^2 \right\}.$$

The explicit form of $\Lambda_{\text{LOD}}$ is shown in Eq. (7) at the top of the next page; the derivation is given in the Appendix.

Counting rule (CR) - this rule is widely used in DF (due to its simplicity and no requirements on system knowledge) and it is obtained by assuming that the communication channels are ideal, i.e.

$$\Lambda_{\text{CR}} \triangleq \sum_{k=1}^{K} y_k,$$

since $P_{e,k} = 0$ entails $\alpha_k(P_1) = P_1$ and irrelevant terms are incorporated in $\gamma$ through Eq. (2).

Wu rule [7] - this rule was proposed by Wu et al. and it was shown to outperform a GLRT rule for all the scenarios considered. We report only the final result and omit the details. First an approximate maximum-likelihood (ML) estimate of $P_D$ is obtained as

$$\hat{P}_D \triangleq \frac{1}{K} \sum_{k=1}^{K} \left( 1 + 2 P_{e,k} \right) y_k - P_{e,k} \right],$$

then the following statistic is employed:

$$\Lambda_{\text{Wu}} \triangleq (P_D - \hat{P}_D).$$

Remark: when $P_{e,k} = P_e$ all the rules are equivalent. Thus, when the SNR goes to infinity (i.e. $P_{e,k} \to 0$) all the rules undergo the same performance. The only exception is $\Lambda_{\text{IS}}$, since $\lim_{P_{e,k} \to 0} \Lambda_{\text{IS}} = +\infty$ (such a difference leads to a loss in performance, as shown in [11]). Differently, in the low SNR regime their behaviour is significantly different, as shown by the following proposition.

Proposition 1. When the SNR is low at each link, $\Lambda_{\text{IS}}$ and $\Lambda_{\text{LOD}}$ approach $\Lambda_{\text{LRT}}$, while $\Lambda_{\text{Wu}}$ does not.

Proof: $\Lambda_{\text{IS}}$ and $\Lambda_{\text{LOD}}$ are equivalent to $\sum_{k=1}^{K} \psi(P_{e,k}) y_k$ and $\sum_{k=1}^{K} \phi(P_{e,k}) y_k$, respectively, where $\psi(P_{e,k}) \triangleq \ln \left( \frac{1 - P_{e,k}}{P_{e,k}} \right)$ and $\phi(P_{e,k}) \triangleq \ln \left( \frac{1 - P_{e,k}}{P_{e,k}} \right)$ (cf. Eqs. (4)). Also, $\Lambda_{\text{LRT}} = \sum_{k=1}^{K} \chi(P_{e,k}) y_k + \psi(P_{e,k}) (1 - y_k)$), where we have denoted $\chi(P_{e,k}) \triangleq \ln \left( \frac{1 - P_{e,k}}{P_{e,k}} \right)$ and $\psi(P_{e,k}) \triangleq \ln \left( \frac{1 - P_{e,k}}{P_{e,k}} \right)$. When the SNR is small, we can approximate each $\psi(P_{e,k})$, $\phi(P_{e,k})$, $\chi(P_{e,k})$, and $\psi(P_{e,k})$ by a first-order Taylor series around $P_{e,k} = \frac{P}{2}$. Exploiting these expansions leads to $\sum_{k=1}^{K} \psi(P_{e,k}) y_k \approx 2 \sum_{k=1}^{K} (1 - 2 P_{e,k}) y_k$, $\sum_{k=1}^{K} \phi(P_{e,k}) y_k \approx 4 \sum_{k=1}^{K} (1 - 2 P_{e,k}) y_k$ and $\Lambda_{\text{LRT}} \approx 2 (P_D - P_F) \sum_{k=1}^{K} [(1 - 2 P_{e,k}) (2 y_k - 1)]$. Then, the Taylor-based approximations at low SNR are all equivalent and thus $\Lambda_{\text{IS}}$, $\Lambda_{\text{LOD}}$ and $\Lambda_{\text{LRT}}$ undergo the same performance. Finally, since $\Lambda_{\text{Wu}}$ is equivalent to $\sum_{k=1}^{K} (1 + 2 P_{e,k}) y_k$ (cf. Eqs. (10)), at low SNR it poorly approximates $\Lambda_{\text{LRT}}$, whose Taylor-based approximation is instead equivalent to $\sum_{k=1}^{K} (1 - 2 P_{e,k}) y_k$.

It is worth noting: (i) Prop. (1) does not require $P_{e,k}$ to be equal and that (ii) the low-SNR optimality of $\Lambda_{\text{IS}}$ in Prop. (1) is coherent with the results shown in [3], [5], [6].

Wu rule vs CR deflection comparison: since all the considered rules are equivalent to scaled sums of independent Bernoulli random variables, the pmf $P(\mathcal{H}|\mathcal{H}_i)$ is tractable [7]. Hence we rely on the so-called deflection measures $D_i \triangleq \frac{\mathbb{E}[(\mathcal{H}_i) - \mathbb{E}[\mathcal{H}_i]|\mathcal{H}_i]}{\mathbb{V}[\mathcal{H}_i]}$ to perform a theoretical comparison between $\Lambda_{\text{CR}}$ and $\Lambda_{\text{Wu}}$. This choice is justified since, as $K$ grows large, $P(\mathcal{H}|\mathcal{H}_i)$ converges to a Gaussian pdf (in virtue of the central limit theorem [13]). It can be shown that for CR and Wu rule the deflections assume the following expressions:

$$D_{\text{CR,i}} = \frac{\sum_{k=1}^{K} m_k}{\sum_{k=1}^{K} c_k}, \quad D_{\text{Wu,i}} = \frac{\sum_{k=1}^{K} n_k m_k}{\sum_{k=1}^{K} n_k^2 c_k},$$

where $m_k \triangleq (1 - 2 P_{e,k})(P_D - P_F)$, $n_k \triangleq (1 + 2 P_{e,k})$, $c_k \triangleq \alpha_k(P_F) (1 - \alpha_k(P_D))$ and $c_k \triangleq \alpha_k(P_D) (1 - \alpha_k(P_D))$. W.l.o.g., we assume $P_{e,k} \geq P_{e,k+1}$, which in turn gives $m_k \leq m_{k+1}$, $n_k \geq n_{k+1}$ and $c_k \geq c_{k+1}$ (since we assume $P_{e,k} \leq \frac{P}{2}$). Consequently, the Chebyshev’s sum inequalities [13] lead to

$$\sum_{k=1}^{N} n_k m_k \leq \frac{1}{K} \left( \sum_{k=1}^{N} m_k \right) \left( \sum_{k=1}^{N} n_k \right), \quad \sum_{k=1}^{N} n_k^2 c_k \geq \frac{1}{K} \left( \sum_{k=1}^{N} c_k \right) \left( \sum_{k=1}^{N} n_k^2 \right)$$

which jointly give:

$$D_{\text{Wu,i}} \leq D_{\text{CR,i}}$$

This was derived under a high-SNR assumption [7].

We use the term “equivalent” to refer to statistics which are equal up to a scaling factor and an additive term (both independent on $y$ and finite), thus leading to the same performance [11].
\[ \Lambda_{\text{LOD}} = \left( \sum_{k=1}^{K} \left( 1 - 2 P_{e,k} \right) \left( y_k - P_{e,k} - (1 - 2 P_{e,k}) P_F \right) \alpha_k(P_F) \beta_k(P_F) \right)^{-1} \]  

(7)

Figure 1. \((D_{\text{CR},0} \sim D_{\text{wu},0})\) for \(K = 2\) sensors as a function of \(\{P_{e,1}, P_{e,2}\}\), conditionally i.i.d. decisions \((P_F, P_D) = (0.05, 0.5)\).

Table I

| Fusion rule   | Required parameters |
|---------------|---------------------|
| (Clairvoyant) LRT | \(P_D, P_F, P_{e,k}\) |
| LOD rule      | \(P_{e,k}\)         |
| IS rule       | \(P_{e,k}\)         |
| CR            | none                |
| Wu rule [7]   | \(P_F, P_{e,k}\)    |

where \(n = [n_1 \cdots n_K]^{\top}\) and the first inequality arises from the application of Cauchy-Schwartz inequality \([15]\) to \[\|n\|_1\].

In Fig. 1 we illustrate \((D_{\text{CR},0} \sim D_{\text{wu},0})\) in a WSN with \(K = 2\) as a function of \(\{P_{e,1}, P_{e,2}\}\) in a scenario with \((P_F, P_D) = (0.05, 0.5)\). It is confirmed that \(D_{\text{wu},0}\) is always dominated by \(D_{\text{CR},0}\) and that the effect is more pronounced when \(P_{e,1}\) and \(P_{e,2}\) differ significantly (indeed when \(P_{e,1} = P_{e,2}\), \(\Lambda_{\text{CR}}\) is equivalent to \(\Lambda_{\text{CR}}\)). The superiority of \(\Lambda_{\text{CR}}\) is also confirmed via the results in Sec. [V].

Discussion on complexity and system knowledge: As discussed in [7], \(\Lambda_{\text{wu}}\) being affine in \(y\) (cf. Eqs. [9][10]) is one of the main advantages w.r.t. the GLRT. This feature reduces the complexity at the DFC and facilitate performance analysis. Since all the considered alternatives (i.e. \(\Lambda_{\text{LOD}}\) and \(\Lambda_{\text{CR}}\)) are also affine functions of \(y\), they exhibit the same advantages. On the other hand, as summarized in Tab. I the presented fusion rules have different requirements in terms of system knowledge. In fact, while \(\Lambda_{\text{LOD}}\) and \(\Lambda_{\text{wu}}\) entail the same requirements (i.e. \(P_F\) and \(P_{e,k}\)), \(\Lambda_{\text{IS}}\) only needs \(P_{e,k}\). Finally, \(\Lambda_{\text{CR}}\) does not require any parameter for its implementation.

IV. EXTENSION TO NON-IDENTICAL SENSORS SCENARIO

In this section we generalize the proposed rules to a scenario with non-identical sensors, i.e. \((P_{D,k}, P_{F,k}), k \in K\), where \(P_{F,k}\) is known but \(P_{D,k}\) is still unknown at the DFC.

(Clairvoyant) LRT - \(\Lambda_{\text{LRT}}\) is readily obtained by replacing \(\alpha_k(P_D)\) (resp. \(\alpha_k(P_F)\)) with \(\alpha_k(P_{D,k})\) (resp. \(\alpha_k(P_{F,k})\)) in Eq. (3).

LOD fusion rule - the rule is naturally extended to conditionally independent and non-identically distributed (i.i.d.) decisions:

\[ \tilde{\Lambda}_{\text{LOD}} = \sum_{k=1}^{K} \frac{\partial \ln [P(y_k; P_{F,k})]}{\partial P_{1}} \bigg|_{P_1 = P_{F,k}} \left( \sqrt{I_k(P_F)} \right)^{-1} \]  

(13)

Figure 2. \(P_{D_0}\) vs. \(P_{F_0}\): WSN with \(K = 10\) and \((\text{SNR}_k)_{\text{IS}} \in \{0, 10\}\) (resp. \((\text{SNR}_k)_{\text{CR}} \in \{0, 10\}\); \((P_{F,k}, P_{D,k}) = (0.05, 0.5)\) (resp. \((P_{F,U}, P_{D,E}) = (0.2, 0.6)\)) for conditionally i.i.d (resp. i.n.i.d.) decisions.

CR, IS and Wu fusion rules - in this scenario \(\Lambda_{\text{IS}}\) retains the same form as in Eq. (4), while it is apparent that \(\Lambda_{\text{CR}} = \sum_{k=1}^{K} y_k\) does not arise from the assumption \(P_{e,k} = 0\) in \(\Lambda_{\text{LRT}}\). Nonetheless we will still keep \(\Lambda_{\text{CR}}\) in the comparison of Sec. [V] since it represents a natural “\(P_{D,k}\)-unaware” alternative. Finally, we discard Eq. (10) from our comparison, since the (approximate) performance of the proposed rules in terms of system false alarm and detection probabilities, defined as \(P_F \triangleq \Pr\{A > \gamma|H_0\}, \quad P_D \triangleq \Pr\{A > \gamma|H_1\}, \) respectively, where \(A\) is the generic statistic employed at the DFC.

Similarly as in [7], we consider communication over a Rayleigh fading channel via on-off keying, i.e. \(x_k = h_k u_k + w_k\), where \(x_k \in \mathbb{C}, h_k \sim \mathcal{CN}(0, 1), u_k \sim \mathcal{CN}(0, \sigma_w^2); h_k\) is assumed known at the DFC and therefore coherent detection is employed. Given these assumptions, \(P_{e,k} = \Theta(\frac{\sigma_w^2}{\sigma_h^2})\) holds. We define the (individual) communication SNR as the (average individual) received energy divided by the noise power, that is in the i.i.d. case

\[ \text{SNR}_k = \frac{\mathbb{E}[|h_k u_k|^2]}{\sigma_w^2} = P_{D,k} P(H_1) + P_{F,k} P(H_0), \]  

while in the i.i.d. case \(\text{SNR}_k = \frac{\mathbb{E}(P_{D,k} + P_{F,k})}{\sigma_w^2}\). Here we assume \(P(H_0) = \frac{1}{2}\); the figures are based on \(0^{10}\) Monte Carlo runs.

In Fig. 2 we report \(P_{D_0}\) vs. \(P_{F_0}\) in a scenario with conditionally i.i.d. and i.n.i.d. decisions, respectively.\(^6\) We study a WSN with \(K = 10\) and local performance equal to \((P_{F,k}, P_{D,k}) = (0.05, 0.5)\) in the i.i.d. case while \(P_{F,k} \sim \mathcal{U}(0, P_{F,U}), P_{D,k} = (P_{F,k} + \Delta P)\) and \(\Delta P \sim \mathcal{U}(0, P_{D,E})\) in the i.i.d. case, where \((P_{F,U}, P_{D,E}) = (0.2, 0.6)\). We report scenarios with \((\text{SNR}_k)_{\text{IS}} \in \{0, 10\}\) (resp. \((\text{SNR}_k)_{\text{CR}} \in \{0, 10\}\) where \(\text{SNR}_{k} = \frac{P_{F,k} + P_{D,k}}{2\sigma_w^2}\) in the i.i.d. case). It is apparent that \(\Lambda_{\text{LOD}}\) and \(\Lambda_{\text{wu}}\) approach \(\Lambda_{\text{LRT}}\) at \((\text{SNR}_k)_{\text{IS}} = 0\) in the i.i.d. case (confirming Prop. [1]), while there is a moderate loss

\(^6\)Note that the concavity of the plots is not apparent, as instead suggested from the theory [11]; this is due to the use of a log-linear scale.

V. NUMERICAL RESULTS

In this section we compare the performance of the proposed rules in terms of system false alarm and detection probabilities, defined as

\[ P_F \triangleq \Pr\{A > \gamma|H_0\}, \quad P_D \triangleq \Pr\{A > \gamma|H_1\}, \]

(14)

respectively, where \(A\) is the generic statistic employed at the DFC.

\(\text{SNR}_k = \frac{\mathbb{E}[|h_k u_k|^2]}{\sigma_w^2} = P_{D,k} P(H_1) + P_{F,k} P(H_0), \)

(15)
achieves alarm probability of the generic sensor, but does not the detection counting rule, thus does not exploit effectively the required system probability. Wu rule is always (counter-intuitively, since it makes use parameters. This result is confirmed by a deflection-based analysis, when

\[ \Lambda \approx \frac{1}{K} \sum_{k=1}^{K} (1 - 4 P_{e,k}^2) \cdot P_{D} + 2 P_{e,k}^2, \]

i.e. when \( P_{e,k} \) is not negligible, the estimator is biased (even if \( K \) grows large), as opposed to the exact ML estimate \([16]\).

Fig. 3 shows \( P_{D0} \) vs. \((\text{SNR})_{dB}\); \( P_{D0} = 0.01 \) when the WSN is not of large size. Moreover the performance of \( \hat{P}_D \) further degrades at low-medium SNR, since

\[ \mathbb{E}[\hat{P}_D|\text{Wu}] = \frac{1}{K} \sum_{k=1}^{K} \left( (1 - 4 P_{e,k}^2) \cdot P_{D} + 2 P_{e,k}^2 \right). \]

Also, in the i.i.d. case \( \Lambda_{LOD} \) is outperformed by both \( \Lambda_{CR} \) and \( \Lambda_{LRT} \), the latter being the best choice. Finally, the oscillating behaviour of \( \Lambda_{Wu} \) is explained since the approximate ML estimate \( P_D \) (cf. Eq. (19)) is not reliable when the WSN is not of large size. Moreover the performance of \( \hat{P}_D \) further degrades at low-medium SNR, since

\[ \mathbb{E}[\hat{P}_D|\text{Wu}] = \frac{1}{K} \sum_{k=1}^{K} \left( (1 - 4 P_{e,k}^2) \cdot P_{D} + 2 P_{e,k}^2 \right), \]

i.e. when \( P_{e,k} \) is not negligible, the estimator is biased (even if \( K \) grows large), as opposed to the exact ML estimate \([16]\).

Fig. 3 shows \( P_{D0} \) vs. \((\text{SNR})_{dB}\); assuming \( P_{D0} = 0.01 \) we simulate a i.i.d. scenario, where \( (P_{F,k}, P_{D,k}) = (0.05, 0.5) \) and we report the cases \( K \in \{10,30\} \). First, simulations confirm the theoretical findings in Sec. III (1) only \( \Lambda_{IS} \) and \( \Lambda_{LOD} \) approach \( \Lambda_{LRT} \) at low SNR, while (ii) all the considered rules undergo the same performance as the CR rule randomization (as opposed to the exact ML estimate \([16]\)).

VI. CONCLUSIONS

In this letter we studied DF when the DFC knows the false-alarm probability of the generic sensor, but does not the detection probability. Wu rule is always (counter-intuitively, since it makes use of BEPs and false alarm probabilities) outperformed by the simpler counting rule, thus does not exploit effectively the required system parameters. This result is confirmed by a deflection-based analysis, with CR always dominating Wu rule, irrespective of the specific

BEPs and local performance (in the i.i.d case) considered. Differently, the proposed LOD and IS based rules are appealing in terms of complexity and performance. LOD rule was shown to be close to the clairvoyant LRT over a realistic SNR range (thus effectively exploiting knowledge of BEPs and false alarm probabilities), both for conditionally i.i.d. and i.i.d. decisions, as opposed to IS rule (only requiring the BEPs for its implementation) being close to the LRT only at low-medium SNR. Optimality of both rules was proved at low SNR in the i.i.d case, thus motivating the knowledge of false-alarm probability only at medium SNR in a homogeneous scenario.

APPENDIX

We start expressing the log-likelihood \( \ln [P(y; P_1)] \) explicitly:

\[ \ln [P(y; P_1)] = \sum_{k=1}^{K} \left\{ y_k \ln \alpha_k(P_1) + (1 - y_k) \ln \beta_k(P_1) \right\} \]

where \( \alpha_k(P_1) \) and \( \beta_k(P_1) \) have the same meaning as in Eq. (16) as opposed to \( K \approx 43 \) when \( \Lambda_{Wu} \) is employed.

On the other hand, we notice that \( I(P_1) = \sum_{k=1}^{K} I_k(P_1) \), where

\[ I_k(P_1) = \mathbb{E} \left\{ \frac{\partial \ln [P(y; P_1)]}{\partial P_1} \right\} \]

(17)

since \( y_k \) are (conditionally) independent. Hence, we can evaluate each \( I_k(P_1) \) separately. Considering the explicit form of \[ \frac{\partial \ln [P(y; P_1)]}{\partial P_1} \] in Eq. (17), squaring and taking the expectation leads to:

\[ I_k(P_1) = (1 - 2 P_{e,k}^2)^2 \mathbb{E} \left\{ \left( (1 - 2 P_{e,k}^2)(P_1 - (y_k - P_{e,k})) \right)^2 \right\}, \]

(18)

The average in the r.h.s. of Eq. (18) is given explicitly as follows:

\[ \mathbb{E} \left\{ (1 - 2 P_{e,k}^2)(P_1 - (y_k - P_{e,k})) \right\} = \alpha_k(P_1) \beta_k(P_1), \]

(19)

which can be substituted in Eq. (13) to obtain \( I_k(P_1) \) in closed form. Summing all the (independent) contributions \( I_k(P_1) \) leads to:

\[ I(P_1) = \sum_{k=1}^{K} I_k(P_1) = \sum_{k=1}^{K} (1 - 2 P_{e,k}^2)^2 \frac{\alpha_k(P_1)}{\beta_k(P_1)} \]

(20)

Finally substituting Eqs. (16) and (20) in Eq. (5) provides Eq. (7).
