Diagnoses from lung specimen collected through flexible bronchoscopy from patients in a tertiary hospital in Dar es Salaam Tanzania: a retrospective cross-sectional study

Deus A. Ndilanha¹, Grace A. Shayo¹* , Ramadhan Hassan², Moses Byomuganyizi² and Leonard E. K. Lema²†

Abstract

Background: Flexible bronchoscopy enables visualization of the respiratory airway mucosa from the oropharynx to third generation branching of the tracheobronchial tree. Bronchoscopic diagnoses vary from one locality to the other in accordance to the locality specific risk factors for lung diseases. This study aimed at describing diagnoses of all specimen of patients who underwent flexible bronchoscopy at Muhimbili National Hospital from January 2013 to November 2017.

Methods: A retrospective hospital-based cross sectional study was conducted among 451 patients. Data was collected from archives and included both demographic and clinical variables. Descriptive statistics were used to summarize the study findings.

Results: There was a 3 fold increase in the number of patients who underwent flexible bronchoscopy from 57 cases in 2013 to 180 cases in 2017. About 39% (174/451) of patients underwent lung biopsies while 64.5% (291/451) underwent bronchioalveolar lavage, bronchial washings or brush cytology, alone or in combination with biopsy. Generally, 64.4% (112/174) of all lung biopsies were malignant. Adenocarcinoma was the most common diagnosis seen in 33.9% (59/174). Of 76 cytological samples which were sent for bacterial culture and sensitivity, 11/76 (11.8%) were culture positive. A total of 6 (10.7%) out of 56 samples which were sent for GeneXpert MTB/RIF tested positive for M. tuberculosis.

Conclusion: Adenocarcinoma was the most common diagnosis. Bacterial and mycobacterial infections were among the most reported findings in cytological samples. Suspicious tuberculosis lesions during bronchoscopy made it possible to diagnose tuberculosis which was hard to diagnose before patients were sent for bronchoscopy.

Keywords: Flexible bronchoscopy, Bronchioalveolar lavage, Brush cytology, Transbronchial biopsy, Cytology, Histology, Tuberculosis, Lung tumors, Lung infections
Background
Flexible bronchoscopy is an endoscopic procedure that utilizes the technique of visualizing the tracheobronchial tree mucosa all the way from the oropharynx to the third generation bronchioles. It is useful both in diagnostic and therapeutic purposes [1]. The diagnostic uses include; bronchoalveolar lavage (BAL) sampling, transbronchial biopsy, bronchial washing or brushing, transbronchial needle aspiration and endobronchial ultrasound. Therapeutically flexible bronchoscopy uses include balloon dilatation, endobronchial laser ablation, electrocautery, photodynamic therapy and at times used for stent placement [1].

The advantages of flexible bronchoscopy over rigid bronchoscope is its ability to access distal airways, easily tolerated by most patients and doesn’t require general anesthesia. Flexible bronchoscope is, however not suitably applied for large and deeper biopsies [2–4].

Bronchial washing specimen obtained during bronchoscopy when coupled with other bronchoscopic sampling techniques gives complementary yield in the diagnosis of lung pathologies [5]. This is particularly so in cases like smear negative Mycobacterium tuberculosis and Pneumocystis jirovecii pneumonia (PJP) whose diagnosis in some patients has become possible only through bronchoscopic procedures [2, 6–8].

Bronchoscopic biopsy is currently the most preferred option compared to open lung biopsy due to its safety and fewer mortality rates [9–11].

Flexible bronchoscopies were done in small scale in Muhimbili National Hospital, the largest tertiary hospital in Tanzania since the year 1991. The year 2014 witnessed an intensive training mentorship of 4 young doctors which was pioneered by the Global Health Service Partnership (GHSP) in collaboration with the Muhimbili University of Health and Allied Sciences. Four other young doctors were subsequently trained making a total of 8. GHSP is dedicated to address global shortage of healthcare professionals by sending physicians and nurses to work alongside institutes aiming at building capacities and hence strengthening the quality of medical education. Ever since, the bronchoscopy unit at the hospital became more structured and bronchoscopies are now being done more regularly than ever. Despite the presence of flexible bronchoscopic procedures for several years in the hospital, the pattern of diseases and conditions diagnosed in Muhimbili National Hospital (MNH) is largely unknown. This study aimed at describing pathological diagnoses of specimen collected from patients who underwent flexible bronchoscopy at MNH from January 2013 to November 2017.

Methods
Study design, site, and population
A retrospective hospital-based descriptive cross-sectional study was conducted at Muhimbili National Hospital (MNH) in Dares Salaam covering a period of 5 years from January 2013 to November 2017. Muhimbili National Hospital is the largest tertiary hospitals in the country. It is located in the Eastern Coast city of Dar es Salaam, which is also the commercial capital city of Tanzania. MNH serves as a University teaching hospital for Muhimbili University of Health and Allied Sciences (MUHAS) and other universities in the city. MNH has pulmonary units in both medical and surgical departments. The units serve patients who are admitted in the hospital and those who come on outpatient basis. Flexible bronchoscopies are done once weekly by both pulmonologists and chest surgeons. On average 3–4 patients were scoped every week. Patients who underwent bronchoscopy either came from medical pulmonology clinic, chest surgery clinic or medical and chest surgery inpatients. Some patients were referred directly for bronchoscopy from other hospitals within or outside Dar es Salaam.

The study utilized archived data of all patients who underwent bronchoscopy from January 2013 to November 2017. Bacterial culture results reported in this study had been read after 48 h of culture. Only samples of patients with suspicious lesions for tuberculosis were sent for GeneXpert MTB/RIF.

Inclusion and exclusion criteria
Specimen which were considered for inclusion in this study had to come from adults aged 18 years or older, who underwent bronchoscopy from January 2013 to November 2017. There was no exclusion criteria.

Data collection procedure
Records of patients who underwent flexible bronchoscopy from January 2013 to November 2017 were obtained from books in the bronchoscopy unit. This included patient’s name, hospital registration number, age, sex and indications for bronchoscopy. Hospital registration number was used to trace patient’s file for extraction of information such as residency, marital status, and confirmation of the indications for bronchoscopy. Using the Hospital registration number and patient’s name, the hospital database was accessed in search of laboratory histopathological, cytological and bacteriological results of bronchoscopic specimen. The obtained results were entered into clinical record forms (CRF).

Data management and analysis
Data were captured into the computer using EPI Info software version 3.0. For analysis, the recorded data were transferred into SPSS version 20. Data were summarized using frequencies and percentages.
Results
A total of 451 patients underwent flexible bronchoscopy. Figure 1 represents patients’ flow. Majority were male, 269/451 (59.6%). The mean (SD) age of the study participants was 54.06 (15.7) years. The age range was between 18 years and 91 years. A total of 283/451 (62.7%) patients were aged 50 years or older. Majority of the patients were married 138/196 (70.4%) and were residing in Dar es Salaam 154/270 (57%). Sixty eighty patients/148 (45.9%) had attained primary education as the highest ever reached education (Table 1).

Trend of flexible bronchoscopy at Muhimbili National Hospital
From 2013 to 2017 a total of 451 bronchoscopy were done at MNH. During this period there were gradual increase in number of bronchoscopy year after year except for the year 2014 where there was a slight drop compared to yesteryear. The year 2017 recorded the highest number of patients who underwent bronchoscopic procedures. Comparatively there were 57 patients who underwent bronchoscopy in 2013 whereas there were 180 patients who underwent bronchoscopy from January to November 2017, a more than 3 fold increase from the 2013 annual number. (Fig. 2).

Indications for bronchoscopy for all patients who underwent bronchoscopy at Muhimbili National Hospital from 2013 to 2017
Bronchoscopy indications were lung tumors in 305/451 (67.6%) patients, bronchiectasis 24/451 (5.3%), unexplained hemoptysis 21/451 (4.7%), mediastinal mass 16/451 (3.5%), cavitory lung diseases 16/451 (3.5%), malignant-effusion 15/451 (3.3%), aspergillosis 15/451 (3.3%), Pneumoconiosis 14/451 (3.1%), unexplained lung collapse 10/451 (2.2%), empyema locules 7/451 (1.6%), atypical pneumonia 5/451 (1.1%) and exploratory bronchoscopy in 3 patients (0.7%) (Table 2).

Table 3 summarizes histological findings of 174/451 patients who underwent tissue biopsy. Of the 174 biopsies done, adenocarcinoma was the most common diagnosis seen in 59/174 (33.9%). Nonspecific acute/chronic inflammation was seen in 37/174 (21.3%), squamous cell carcinoma 26/174 (14.9), carcinoma not otherwise specified 16/174 (9.2%) and small cell carcinoma 10/174 (5.7%). A total of 13/174 (7.5%) samples were deemed inadequate and
thus did not yield any results. Sarcoidosis, Aspergillosis and *M. tuberculosis* were the least found histological findings accounting to 1.7, 1.1 and 1.1% respectively. One case of Kaposi’s sarcoma was reported (0.6%) (Table 3).

Cytological findings for all patients with Bronchoalveolar lavage, brush cytology or bronchial washing from 2013 to 2017

A total of 291 patients out of 451 underwent fluid sampling for cytological analysis. The respiratory fluid samples were either collected through bronchoalveolar lavage or

### Table 1 Socio-demographic characteristics of study patients (N = 451)

| Characteristics | Number | Percentage |
|-----------------|--------|------------|
| Sex             |        |            |
| Male            | 269    | 59.6       |
| Female          | 182    | 40.4       |
| Age             |        |            |
| 18–29           | 34     | 7.5        |
| 30–39           | 50     | 11.1       |
| 40–49           | 84     | 18.6       |
| 50–59           | 102    | 22.6       |
| 60+             | 181    | 40.1       |

| Exploratory bronchoscopy        | 3      | .7         |
| **Total**                       | 451    | 100.0      |

Fig. 2 Bronchoscopy trend at Muhimbili National Hospital from 2013 to 2017
bronchial washing or brush cytology. Majority (199/291, 68.4%) of the findings were nonspecific acute/chronic inflammation. There were 45/291(15.5%) cytological samples which were labeled acellular. Malignancy was found in 28/291(9.6%) of fluid specimen, normal respiratory cells were reported in 11/291(3.8%).

*M. tuberculosis* 3(1.0%) and fungal infection 5(1.7%) were the least findings of all fluid samples reported (Table 4).

**Bacteriological findings among patients who underwent bronchoalveolar lavage, brush cytology or bronchial washing (n = 157)**

A total of 157 samples were taken for bacteriological analysis out of 291 fluid specimens. A total of 25/157(15.9%) underwent gram staining. There was a predominance of gram positive cocci in 15/25(60%) patients while gram negative cocci and bacilli were seen in 16% each. Among the cytological samples sent for bacteriological analysis, 76 samples were sent for culture analysis, no growth was reported in 49/76(64.5%), normal flora was reported in 18/76 (23.7%). *Pseudomonas aeruginosa* was reported in 4/76 (5.3%), *Streptococcus pneumoniae* was reported in 3/76 (3.9%) while *Escherichia coli* was found in 2(2.6%).

A total of 56 samples were sent for *Mycobacterium tuberculosis* diagnosis through Gene Xpert MTB/RIF molecular technique. Of these, 6(10.7%) samples detected *Mycobacterium tuberculosis* (Table 5).

**Discussion**

This study has demonstrated a trend of progressive increase in the number of patients who underwent bronchoscopic procedures at Muhimbili National Hospital (MNH). This trend is attributable to availability of trained bronchoscopists. It was found that majority of the patients who underwent flexible bronchoscopy in the successive period of 5 years were male aged 50 years or older, signifying that old men are the predominant candidates for flexible bronchoscopic procedures in MNH.

It was unfortunate that results for 35 patients were not traceable while 5 specimen were not processed at all after having been labeled inadequate for analysis. With increasing number of bronchoscopic procedures, there should be increased keenness in handling patients’ specimens and results.

Lung tumors were the leading indications for flexible bronchoscopy in MNH, similar to studies in India [12] and Egypt [13]. Generally, about 2/3 (63%) of patients had a diagnosis of lung malignancy. This finding concurs with the previous report that lung tumors are the most common indication for flexible bronchoscopy in MNH [11].

**Table 3** Histological findings for patients who underwent flexible bronchoscopic lung biopsy at Muhimbili National Hospital from 2013 to 2017, n = 174

| Histopathological diagnosis                  | Number | Percentage |
|----------------------------------------------|--------|------------|
| Adenocarcinoma                               | 59     | 33.9       |

MTB Mycobacterium tuberculosis, RIF Rifampicin
with findings from other studies that found lung malignancies in 64–82% of patients who underwent bronchoscopy [14]. Lung biopsies revealed that adenocarcinoma was the most common lung cancer followed by squamous cell carcinoma, carcinoma not otherwise classified, and small cell carcinoma. The predominance of adenocarcinoma in this study is similar to other recent study findings carried in United States of America, Norway and Japan where the most common malignancy was found to be adenocarcinoma, followed by squamous cell carcinoma and undifferentiated malignancy [14–16]. The study findings also tallies with recent European countries cohort studies which found an increase in the proportion of patients with adenocarcinoma among all histological subtypes [17–19]. There are a number of theories that have been put forward to explain the changes from Squamous cell carcinoma as the predominant lung malignancy up until 1980’s and the rise of adenocarcinoma as the predominant lung malignancy in the recent years in studies held in developed countries. One hypothesis is the use of low tar cigarette filters and taking large puffs to attain a satisfactory desire. These two consequently cause escapement of small particles deeper into the periphery of the lungs and thus the formation of adenocarcinoma [18, 19]. Furthermore filtered cigarettes are said to contain large amounts of nitrates. Nitrates have been found in large amounts in induced adenocarcinomas in animal studies. Air pollution especially of oxides of nitrogen has been attributed to 3% of lung cancers [2, 16, 19]. Unexplained hemoptysis and pneumonia were among the most common indications for bronchoscopy in the present study, both have also been reported as indication for flexible bronchoscopy in other studies [2, 20, 21].

Majority (68.4%) of the specimen of bronchoalveolar lavage and bronchial washings revealed inflammatory process, a finding similar to a study in Greece [21]. This finding suggests that probably most of these patients could benefit from the use of antibiotics, however this supposition doesn’t refute the fact that malignancy process almost always predisposes a person to infection.

Cytological samples identified malignancy in about 10% of patients. This low percentage might be due to the fact that very distal lesions might be hard to reach as well as fewer cytology samples were from brush cytology.

Fungi and *M. tuberculosis* infections were also picked in low percentages by the cytological samples. The low percentage for *M. tuberculosis* could partly be due to the fact that at MNH patients sent for bronchoscopy needed to be free of active tuberculosis, thus patients who underwent bronchoscopy were actively screened for active tuberculosis and declared tuberculosis free before the procedure was done. Furthermore, not all cytological samples were sent for *M. tuberculosis* or microbiological tests unless a clinician doing bronchoscopy had a suspicion for active TB infection. One study that aimed to diagnose tuberculosis through bronchoscoalveolar lavage (BAL) and transbronchial lung biopsies among patients with high risk for HIV infection isolated tuberculosis in 48% of the cases [22]. A study in South Africa by Khan et al revealed that multiple TB microbiologic tests improved diagnostic yield of BAL from 47 to 74% compared to culture alone [23]. We believe that if BAL was subjected to other microbiologic tests in conjunction with GeneXpert more TB could have been diagnosed. Thus, expanding bronchoscopy services in Tanzania will help in the diagnosis of complex lung diseases including TB diagnosis among immunodeficient patients.

**Conclusion**

This study has demonstrated that bronchoscopic procedures have been increasingly performed at Muhimbili National Hospital in the past 5 years. Lung tumor was the leading indication for bronchoscopy. Adenocarcinoma was the most diagnosed malignancy. Bacterial and mycobacterial infections were among the most reported findings in cytological samples. This finding suggests a consideration of bronchoscopy for TB diagnosis in suspected patients in whom other diagnostic tests have turned negative. Screening for *M. tuberculosis* should be aggressive including sputum induction in those who can’t produce sputum prior to bronchoscopy to minimize number of TB patients in the bronchoscopy room.

**Study limitation**

This was a retrospective study which solely depended on archived data thus inherent limitations like missing data or specimen were common. This might in a way have affected the results.
