Abstract

The fabrication and performance of an ultrafine silver (Ag) grid film applied to flexible touch sensor as the transparent conductive electrode is reported. The ultrafine Ag grid film was fabricated based on the laser direct writing, electro-forming, nano-imprint lithography. In the manufacturing process, firstly, the Nickel (Ni) mold used as the master mold was obtained by laser direct writing and electroforming technologies. Secondly, the micro-grooves were transferred from the Ni mold onto the surface of UV glue coated on the polyethylene terephthalate film through nano-imprinting technology. Lastly, the ultrafine Ag grid was generated through nano-imprint lithography with Ag paste filled into the micro-grooves on the UV glue. The result indicated that the ultrafine Ag grid film with size (L) 640 mm × (W) 520 mm had a uniform line width of 1.01 μm and showed excellent optoelectronic and mechanical properties, such as optical transmittance 90.00%, Haze 1.49%, sheet resistance 5.4 Ω/□, the variation ratio of the sheet resistance within 3% after 8000 bending cycles, and the almost negligible morphology change after the adhesion cross-cut test. Furthermore, the functional test was performed on a flexible touch sensor applying the ultrafine Ag grid film.

Keywords Ultrafine silver grid film · Flexible touch sensor · Transparent conductive electrode · Nickel mold · Laser direct writing

1 Introduction

As a pivotal component of many photoelectric products described by Chung et al. [1] including solar cells studied by Yang et al. [2], liquid crystal displays (LCDs) reported by Blake et al. [3], organic light-emitting diodes (OLEDs) shown by Wu et al. [4] and touch screen panels (TSPs) discussed by Jeon et al. [5] and Kim et al. [6], conductive electrodes have attracted more and more attention. Indium tin oxide (ITO) is the most widely used transparent conductive electrode material owing to its excellent optoelectronic properties. However, as Hecht et al. [7] and Kwon et al. [8] proposed, many new applications have been limited due to its disadvantages, such as its brittleness and scarcity. Because of the flexible, abundant and cost-effective, transparent conductive electrode material will undoubtedly become an irresistible trend, which researched by Tang et al. [9], Li et al. [10] and Lai et al. [11].

Thus, the next generation of material with superior flexibility and abundant resources, without damaging the optoelectronic properties of transparent conductive electrode materials, is urgently needed. Current researches on alternative materials mainly focusing on carbon nanotubes reported by Yu et al. [12], graphene described by Bae et al. [13] and Tung et al. [14], conducting polymers investigated by Kirchmeyer and Reuter [15], polymer composite to improve the long-term stability of the conductive film was researched by Jiang et al. [16, 17], metal nanostructures shown by Gaynor et al. [18], Hong et al. [19] and Madaria et al. [20]. While the conductivity and

Genchu Tang, tanggenchu@ofilm.com | 1Postdoctoral Programme of O-Film Technology Co., Ltd., Nanchang 330032, People’s Republic of China. 2O-Film Technology Co., Ltd., Nanchang 330032, People’s Republic of China.
transmittance of carbon nano-materials are poorer than those of metal nanostructures, the same with the conductivity and stability of conducting polymers based on the researches of Hecht et al. [7] and Kumar and Zhou [21]. And metal nanostructures, such as Ag nanowires or grids, have been successfully applied in touch screen panel based on the reports of Madaria et al. [20], Hong et al. [22] and Hyunjin et al. [23]. However, there are still shortcomings in a few crucial properties of the Ag nanostructures in their reports, such as the line width of Ag nanowires, optical transmittance and haze, sheet resistance, mechanical stability and so on. Therefore, the further improvement of these properties will be critical to the effective application of Ag nanostructures in the practical industrial manufacturing.

In the present work, the fabrication and performance of an ultrafine silver (Ag) grid film applied to flexible touch sensor as the transparent conductive electrode was introduced. In order to improve the deficiencies of the above mentioned properties, and realize the application of Ag nanostructures in the large-area, high-throughput and low-cost production of flexible touch sensor. The ultrafine Ag grid film was fabricated based on the laser direct writing, electroforming, nano-imprint lithography. In the manufacturing process, the Nickel (Ni) mold used as the master mold was obtained by laser direct writing and electroforming technologies, and the micro-grooves were transferred from the Ni mold onto the surface of UV glue coated on the polyethylene terephthalate (PET) film through the nano-imprint lithography. Moreover, the ultrafine Ag grid was generated through nano-imprint lithography with Ag paste filled into the micro-grooves on the UV glue and baked at 130 °C for 1 h. In addition, the properties of the fabricated ultrafine Ag grid film were well studied and performed in order to evaluate the possibility of the fabricated ultrafine Ag grid film substituting for the conventional ITO electrode, and being adopted as a promising transparent conductive electrode applied to the flexible touch sensor.

2 Experimental

2.1 Fabrication of Ni mold

The Ni mold played an important role in the nano-imprinting process, especially the performance of the ultrafine Ag grid film was determined by the accuracy of the pattern on mold. In this work, the fabricated process of the Ni mold can be divided into the following five steps, and the experimental parameters corresponding to each step are the optimal values obtained from a series of optimization experiments before the actual mass production.

Firstly, the positive photosresist (PR, xingtek, China, 0.7 μm) was coated in 1 μm thickness onto the glass substrate ((L) 670 mm × (W) 550 mm × (T) 4.8 mm) by spin-coating, then baked at 100 °C for 60 s (Fig. 1a). Secondly, the laser direct writing scanning was performed with the positive PR side of the sample exposed to Laser, the energy density and laser exposure accuracy of the corresponding laser direct writer (DWL, Heidelberg Instruments, German) are 140 mJ/cm² and 700 nm, respectively (Fig. 1b). Thirdly, the sample was developed in the developer solution for 50 s at 25 °C (Fig. 1c), then baked for 0.5 h at 120 °C. Fourthly, as shown in Fig. 1d, a thin layer of Ni film was vapor deposited onto the pattern on the positive PR as the cathode of the subsequent electroforming process, and the schematic diagram of the vacuum evaporation device is shown in the top right corner of Fig. 1d. The vacuum evaporation refers to a layer of Ni with a thickness of about 20–50 nm deposited onto the pattern on the positive photoresist. The highly purified Ni target materials and extremely cleanliness of the vacuum evaporation device are important guarantee for the quality of evaporation. Finally, as shown in Fig. 1e, the Ni mold was generated on the cathode of the electrolytic cell through electroforming technology, meanwhile the schematic diagrams of the electroformed product (the upper part is the corresponding profile of the sample) and electroforming device are shown in the lower left corner and upper right corner of Fig. 1e, respectively. The electroforming process means that the positive photoresist with the surface of evaporated Ni is placed in the electrolytic cell, a layer of Ni with a thickness of about 0.2 mm is electroformed on the positive photoresist, and the positive photoresist is peeled off to obtain the Ni mold. The size of the generated Ni mold was (L) 640 mm × (W) 520 mm × (T) 200 μm.

2.2 Fabrication of ultrafine Ag grid film

The following fabricated process of the ultrafine Ag grid film in this work can be divided into the following three steps.

Firstly, a UV curable synthetic resin (UV glue) prepolymer was coated on the surface of obtained Ni mold, and a PET film with size (L) 640 mm × (W) 520 mm × (T) 23 μm was imprinted with the UV glue by roller. In this process, the coating thickness of the UV glue was directly determined by the viscosity of UV glue, the pressure and rotation speed of the roller. In order to accurately obtain the expected UV glue thickness, a series of inquiry experiments on the relationship between these three impact factors and the coating thickness of the UV glue had been conducted, meanwhile the corresponding relationship model between them was established.
Fig. 1 The fabrication process of Ni mold in this work: a Positive PR coated onto the glass substrate by spin coating; b Exposure by Laser; c Developing process; d Vacuum evaporation process; e Electroforming process.
Secondly, the UV glue was cured by exposure to the UV light with an energy density of 600 mJ/cm² as shown in Fig. 2a (the upper part is the corresponding profile of the sample), then the micro-grooves were perfectly transferred from the Ni mold onto the UV glue coated on the PET film after the peeling between the PET with UV glue and Ni mold as shown in Fig. 2b. In this process, the peeling effect was directly determined by the energy density of the UV light, an inappropriate UV light energy density would lead to not only the poor peeling effect, resulting in a poor product, but also the block of the micro-grooves on the Ni mold caused by the residual UV glue, resulting in damaging the Ni mold. In addition, after the peeling process, the surface of the cured UV glue was re-exposed by the UV light with much higher energy density to make sure the product with excellent function and appearance can be obtained in the subsequent printing process.

Lastly, the ultrafine Ag grid film was obtained with the Ag pastes filled into the micro-grooves on the UV glue (Fig. 2c) and baked at 130 °C for 1 h. In this process, the function and appearance of the product are determined by the pressure and speed of the squeegee used for printing, the leveling of the printing table, the time interval and the wiping force after the printing, the time and temperature of the post-bake, thus the experimental parameters corresponding to each step are the optimal values obtained from a series of optimization experiments before the actual mass production.

3 Results and discussion

3.1 Characterization of the micro-grooves

As the basis of the ultrafine Ag grid, the micro-grooves play an important role throughout the manufacturing process. Moreover the detailed description of the micro-groove is shown as follows. Figure 3 shows the images of the micro-grooves on the UV glue coated on the PET film. As shown in Fig. 3a, there are 12 units on the PET film, and the units with special pattern can be designed for various touch sensors. Moreover, the micro-grooves in the patterns are of the same specification. Figure 3b, c are the micrographs of micro-grooves in different enlarged scales observed with the scanning electron microscope (SEM, S-4800, Hitachi, Japan), it could be found that the micro-grooves are uniform, and the pitch and angle is 181.0 μm and 19.9°, respectively. In this work, the sheet resistance is 1.95 Ω/□ at the angle 19.9°, which is much lower than most of the reported sheet resistances of transparent conductors used in flexible applications. In the comparative experiments, the sheet resistance is 9.3 Ω/□ at the angle 60°, the sheet resistance is 5.4 Ω/□ at the angle 45°, and the sheet resistance is 3.1 Ω/□ at the angle 30°. Furthermore, the micro-grooves in the rhombus pattern at the angle 19.9° can improve the pixel resolution, and also solve the interference effect of moire fringes. Figure 3d illustrates the measurement of the width (1.01 μm) and depth (1.02 μm) of a micro-groove on the UV glue observed with the shape-measuring laser microscope (SLM, VK-X 210, Keyence, Japan).
3.2 Characterization of the ultrafine Ag grid film

3.2.1 Morphological characterization

To make the ultrafine Ag grid film have good electrical conductivity, and effectively reduce the residual of Ag paste on the non-grooves region during the process of filling grooves with Ag paste, the Ag particle size of the Ag paste in this work mainly distributed in the ranges of 200–300 nm (27.86%) and 300–400 nm (29.10%) shown in Fig. 4 was selected, it also can be seen from Fig. 5 that the micro-shapes of the used Ag particles were irregular, the size of the Ag particles was measured by the Mastersizer 3000 Particle Size Analyzer from Malvern Panalytical. Once the Ag paste was drawn into the groove by a doctor blade under a certain pressure and inclination angle, which was filled into the micro-grooves and baked at 130 °C for 1 h, the ultrafine Ag grid film was generated. The micrograph of the ultrafine Ag grid is shown in Fig. 6a, and it can be seen that the Ag particles were filled fully in the micro-grooves and had good contact with the micro-grooves. The micrograph of the sintered structure of Ag grid is shown in Fig. 6b, the width and depth of a micro-groove is 3.0 μm, respectively. The measurement of the width and depth of the sintered structure of Ag grid is 2.841 μm and 2.023 μm, respectively. The percentage of the area is effectively covered with Ag is calculated by $P = \frac{\text{the width of the sintered structure of Ag grid} \times \text{the depth of the sintered structure of Ag grid}}{\text{the width of a micro-groove} \times \text{the depth of a micro-groove}}$, and the percentage is 63.86%.

3.2.2 Optical performance

The optical properties of PET film and PET + Ag grid film in the visible wavelengths (380–780 nm) are shown in Table 1. It can be seen that the transmittance of PET + Ag grid film is 90.00%, which is very close to that of PET film (90.21%). Moreover, it is well known that the values of “L”, “a”, “b” reflect the degrees of materials between brightness and darkness, red and green, yellow and blue, respectively. The values of “L”, “a”, “b” of PET film are 96.13, 0.17 and 0.50, respectively. And those values of PET + Ag grid film are 96.09, 0.00 and 0.66, respectively. This shows that both the PET film and PET + Ag grid film in this work have excellent chromaticity for the application to flexible touch sensor. Furthermore, after the filling of Ag paste, the optical reflectance (R) was effectively reduced from 11.43 to 10.34% in the visible wavelengths, which is an advantage enhancement to the application of the ultrafine Ag grid film to the flexible touch sensor. In addition, based on Fig. 7, it can be concluded that the optical transmittance (T) and reflectance (R) of PET + Ag grid film fluctuate less than those of PET film in visible wavelengths. Although, the haze (1.49%) of PET + Ag grid film is higher than that (0.34%) of PET film, which is still an excellent value of haze compared to the haze range of 2–6.1% reported by Hyunjin et al. [23].

3.2.3 Mechanical and electrical properties

For the flexible application, the mechanical stability of the transparent conductive electrode is very important. The mechanical stability of the fabricated ultrafine Ag grid film was detected by cyclic bending test and adhesion cross-cut test. A homemade device for the cyclic bending test is shown in Fig. 8a. The compressive strain was applied for thermomechanical bending, the bending direction was relative to the line pattern, the bending axis passed through the center of the channel and was perpendicular to the channel direction. The device includes two parallel metal plates, one plate is fixed, and the other plate can move back and forth. The bending of the PET + Ag grid film is achieved by fixing one end of the film on the fixed plate of the device, and fixing the other end of the film on the moved plate of the device, which moves at a proper frequency (f). The bending
frequency is 1 Hz, and the resistance was recorded during the bending test. The radius of curvature (r) is 2 mm at the maximum bending deformation, the distance between the two plates of the device is minimal at the moment. The photographs of the minimum and maximum bending deformations are shown in Fig. 8b, c, respectively. The average sheet resistance is 5.4 Ω/□,

which is much lower than most of the reported sheet resistances of transparent conductors used in flexible applications. The plots of the sheet resistance (R□) and the corresponding variation ratio of the sheet resistance (ΔR□/R□) with bending times are shown in the Fig. 9. It can be seen from Fig. 9, that the sheet resistance is basically unchanged throughout 1000 bending cycles, the sheet resistance gradually increases throughout 2000 bending cycles, and the changed value of the sheet resistance was within 3% of the primary sheet resistance (from 5.33 to 5.49 Ω/□) throughout 8000 bending cycles, the increased resistance may be the result from the contact resistance between Ag particles. Moreover, compared with the reported data in the literatures, the 8000 bending cycles is 60% higher than the 5000 bending cycles reported by Hong et al.[22], and the radius of curvature (2 mm) at the maximum bending deformation is only 2/15 of theirs (15 mm). 3D microscope shows that the surface roughness of the conductive films is 0.12 μm, which is a low roughness level, indicating that the conductive film surface is very smooth.

In order to further study the adhesion of the ultrafine Ag grid on PET film, the adhesion cross-cut test was conducted on the PET + Ag grid film. The images of PET + Ag grid film after the adhesion cross-cut test (3 M tape, Scotch) are shown in the Fig. 10. Figure 10a, b respect the macrograph and micrograph of PET + Ag grid film after the adhesion cross-cut test, respectively. Based on the images in the Fig. 10, it can be concluded that the change in the morphology of the ultrafine Ag grid film is almost negligible after the adhesion cross-cut test, which not only shows the excellent adhesion between the ultrafine Ag grid and PET film, but also shows the excellent adhesion between the Ag particles making up the ultrafine Ag grid.
3.2.4 Functional test

Based on the above studies, the fabricated ultrafine Ag grid transparent conductive film shows excellent optoelectronic and mechanical performances. Furthermore, the function of the flexible touch sensor applying this film was studied. The functional test was performed on the flexible touch sensor by connecting it with the functional test fixture through a flexible printed circuit board (FPCB). The control chip (ZT7538) in the test fixture was provided by Zinitix Co., Ltd (Korea). The performance of the flexible touch sensor was presented by writing the letters “O-film”, Wavy lines and straight lines on it, as shown in the Fig. 11. It can be seen that the letters and lines are well displayed on the display, and the widths of the lines on display could be changed smoothly when the writing force of the pen changed. Thus, it can be concluded that the fabricated flexible touch sensor worked successfully, and the fabricated ultrafine Ag grid film is a promising transparent conductive electrode that can substitute for the conventional ITO electrode applied in the large-area, high-throughput and low-cost production of flexible touch sensor.

4 Conclusions

In summary, we have demonstrated the fabrication and performance of an ultrafine Ag grid film applied to flexible touch sensor as the transparent conductive electrode. The ultrafine Ag grid film was fabricated based on the laser direct writing, electroforming and nano-imprint lithography, and the maximum size of the ultrafine Ag grid transparent conductor is (L)
640 mm × (W) 520 mm. The fabricated ultrafine Ag grid transparent conductive film shows excellent optoelectronic and mechanical properties, such as line width 1.01 μm, transmittance 90.00%, haze 1.49%, sheet resistance 5.4 Ω/□, the variation ratio of the sheet resistance within 3% after 8000 bending cycles and the almost negligible morphology change after the adhesion cross-cut test. Moreover, the flexible touch sensor applying this film was fabricated and worked successfully, as well as could identify the writing force. Thus, the fabricated ultrafine Ag grid film is a promising transparent conductive electrode that can substitute for the conventional ITO electrode applied in the large-area, high-throughput and low-cost production of flexible touch sensor.
