(Dated: 17 November 2010)

At low strain, SiGe films on Si substrates undergo a continuous nucleationless morphological evolution known as the Asaro-Tiller-Grinfeld instability. We demonstrate experimentally that this instability develops on Si(001) but not on Si(111) even after long annealing. Using a continuum description of this instability, we determine the origin of this difference. When modeling surface diffusion in presence of wetting, elasticity and surface energy anisotropy, we find a retardation of the instability on Si(111) due to a strong dependence of the instability onset as function of the surface stiffness. This retardation is at the origin of the inhibition of the instability on experimental time scales even after long annealing.

The complexity of electronic devices has grown extensively during the last decades. The fundamental limitations for further device improvement challenge the physical mechanisms at stake in the nanoscales. In CMOS technology, silicon-germanium (SiGe)-based materials have shown to overwhelm silicon-only materials and to compete seriously with the high performances of III-V compounds (cut-off frequencies, current gain...).

The fundamental limits to device scaling have been identified at the end of the 1h long growth, and produces a retardation of the instability on Si(111) due to a strong dependence of the instability onset as function of the surface stiffness.

Growth experiments were performed by Molecular Beam Epitaxy (MBE) in a Riber system with a base pressure of ∼10-11 Torr. After 950°C in situ flashing, a Si buffer layer 50 nm thick is deposited at 750°C to provide a perfectly clean reproducible flat surface. Si flux is obtained from an electron beam evaporator and maintained constant during the growth at ∼0.1 ML/s. Ge is deposited from an effusion cell. The growth temperature is 550°C and the Si0.85Ge0.15 composition corresponds to a low misfit (∼0.6%) where the elastic instability occurs during growth without onset of island formation. Silicon substrates are rotated during the experiments and their temperature is real time recorded. Morphologies z=h(x, y) are analyzed after growth by atomic force microscopy (AFM) in air in contact and no contact modes. These evolutions were investigated on Si(001) and Si(111) just after growth and after in situ thermal annealing at 550°C (up to 20h). In the present work the thickness (130 nm) and composition (x = 0.15) of the SiGe layers were adjusted to maintain the structures below the critical thickness of dislocation while providing enough strain energy to develop the instability.

FIG. 1. (color online) AFM top-view images of 130 nm-thick as-grown Si0.85Ge0.15 layers (a) on (001) Si substrate and (b) on (111) Si substrate; side views are shaped in (c) and (d) respectively.

The surface of 130 nm thick Si1−xGe_x films just after growth on Si(111) and Si(100) are displayed in Fig. 1. On Si(001), the elastic instability is already fully developed at the end of the 1h long growth, and produces a
periodic corrugation characterized by a root mean square roughness \( w = \sqrt{(h - \langle h \rangle)^2} \) equal to \( w = 1.87 \text{ nm} \). On the contrary, the experiment performed in the same experimental conditions on a Si(111) substrate leads to an almost flat surface with an intrinsic noise characterized by \( w = 0.33 \text{ nm} \). To investigate the influence of kinetics on the onset of the instability, 20 h long annealing of the 2D film deposited on Si(111) was performed which result is displayed in Fig. 2. Annealing did not allow for the development of the instability, since the resulting film is not significantly changed and is characterized by a roughness with \( w = 0.32 \text{ nm} \).

To give some insights into the reported difference, we turn to the modelling of the ATG instability which is driven by the elastic relaxation enforced by a surface corrugation. Its description involves a continuum representation of surface mass currents, \(^4,5\) where the film height \( h(x, y, t) \) evolves due to gradients in the chemical potential. The latter includes a surface energy \( \gamma(h, n) \) which dependences on \( h \) and on the normal to the surface \( n \) reflect respectively wetting interactions and crystalline anisotropy. \(^9\) For simplicity, we consider \( \gamma(h, n) = \gamma_f [1 + \gamma_k(h) + \gamma_n(n)] \) where \( \gamma_f \) is a reference surface energy. The elastic chemical potential may be computed in the small-slope approximation in terms of the system Green function and of the difference between the film and substrate lattice parameters \( a \).\(^6,9\) One can then define the length scale \( l_0 = \gamma_f (1 - \nu)/[2(1 + \nu)E(1 - \nu/a^2)] \) and time scale \( t_0 = l_0/(\gamma f D) \) where \( \nu \) and \( E \) are the film Poisson ratio and Young modulus, and \( D \), the surface diffusion coefficient. The evolution equation at first order in \( h \) is then

\[
\frac{\partial h}{\partial t} = -\Delta \left\{ \gamma(n, h) \Delta h + h_{ij} \frac{\partial^2 \gamma}{\partial n_i \partial n_j} \frac{\partial \gamma}{\partial h} + \mathcal{H}_{ii}(h) \right\},
\]

with \( i, j = x, y \) and where the first and second term in the bracket describe the anisotropic surface energy, and the third term, the wetting interactions. The elastic energy density is given by the Hilbert transform \( \mathcal{H}_{ii} \) which acts in Fourier space as a multiplication by \( |k|^2 \).\(^9\)

The solution for \( h \), with average \( h_0 \), is given in Fourier space by \( \hat{h}(k, t) = \hat{h}(k, 0) \exp(\sigma t) \), with the growth rate

\[
\sigma(k; n_0, h_0) = -\frac{\partial^2 \gamma}{\partial n^2}(h_0) k^2 + |k|^3 - \hat{\gamma}(n_0) k^4,
\]

where the first and last term describe the stabilizing wetting interactions and surface energy, and the second term, the long-range destabilizing elastic interactions. Anisotropy is embedded in the relative stiffness \( \hat{\gamma}(n) = [\gamma + \partial^2 \gamma/\partial h^2 + \partial^2 \gamma/\partial n^2]/\gamma_f \) which is computed in \(^2\) at \( n_0 \), the substrate orientation.\(^10\) Finally, we fit atomistic calculations\(^11\) with \( \gamma_f(h) = c_0 \exp(-h/a^2) \), where, the variation for Ge on Si gives the extrapolation \( c_0 = 0.05 \) for \( x = 0.15 \). In order to understand the dramatic difference of the film evolution between \( (001) \) and \( (111) \) orientations, we focus on the influence of the surface stiffness on the instability onset, which is known to differ markedly between these orientations.

To study the thermodynamic stability of the film, we first consider the critical height \( h_c \) above which the morphological evolution may happen as the energy of the corrugated layer becomes lower than the one of a flat layer. We define \( h^* \) above which \( \sigma(k) \) given in Eq. (2) displays a local maximum beside \( k = 0 \), and which depends logarithmically on \( \hat{\gamma} \) due to the exponential dependence of \( \gamma_f \).

Considering this conclusion, we now study the dynamics of the instability. We look for the time \( t_d \) where the transition between the flat fully-strained and the corrugated layers experimentally occurs. We characterize the emergence of the instability by the criterion that the roughness is greater than some value \( w_0 \).

Given the solution (2) for \( h \) at linear order, the roughness at time \( t \) is given by \( w^2 = (2\pi/L)^2 \int d^2k \left| |h_1(k, 0)|^2 \exp(2\sigma t) \right| \), where \( L \) is the system size in the \( x \) and \( y \) directions. We consider for the surface initial condition, a white noise of roughness \( w_0 \) distributed on \( L^2 \) modes. The criterion for the instability to be observable is then merely

\[
w^2/w_0^2 = (2\pi)^{-2} \int_{|k_x, k_y|<\pi} d^2k \epsilon^2 |\sigma(k)| t,
\]

FIG. 2. (color online) (a) AFM top-view image of 130nm-thick Si_{65}Ge_{15} layers on (111) Si substrate after 20 h anneal; Side view is shaped in (b).

FIG. 3. Critical height (in ML) above which the elastic instability may develop as function of the surface stiffness \( \hat{\gamma} \).
which can be numerically computed, leading to the time $t_d$ for the onset of the instability.

The resulting $t_d$ for a thick film as function of the surface stiffness is plotted in Fig. 4, considering the threshold $w_d/w_0 = 5$. We find that $t_d$ increases markedly over a small increase of $\gamma$, becoming rapidly beyond experimentally reachable time scales for relatively modest stiffnesses, revealing a notable retardation of the instability dynamics induced by the surface stiffness. The inhibition of the elastic instability on Si(111) may hence be attributed to this stiffness-induced retardation as the (111) orientation is known to be stiffer than the (001) orientation. This higher stiffness of Si(111) is due both to a higher step formation energy, between 0.01 eV and 0.15 eV for the two different step edges on Si(001) and 0.19 eV on Si(111), and lower step diffusivity (inversely proportional to the step stiffness)\textsuperscript{4} 1Å on Si(111) and 15Å on Si(001). As shown in Fig. 4, the evolution of $t_d$ with $\gamma$ is so large that the system may reach during growth the critical thickness for dislocation nucleation before the onset of the morphological evolution. Hence, we attribute the transformation during growth on Si(111)\textsuperscript{5} of 2D layers into dislocated 2D layers to this phenomena.

Our conjecture about the stiffness-induced retardation is also supported by the evolution of SiGe layers on vicinal substrates.\textsuperscript{18} On vicinal Si(001) substrates the ATG instability follows the same morphological evolution than on nominal substrate, but undergoes a morphological change with the transformation of square based ripples into 1D elongated ripples.\textsuperscript{19} On the other hand, on vicinal Si(111) (when the angle exceeds $1^\circ$), the onset of a step bunching instability at low misfits\textsuperscript{19} which relaxes strain through edge effects is observed as opposed to the case on nominal substrate reported above. Considering the strong effect of the atomic steps on Si(111) which enforce a much lower stiffness of the vicinal surface as compared to the nominal one, we advocate that the surface stiffness is the essential parameter ruling the dynamics of strained films.

If a crucial difference between the (001) and (111) orientations concerns their stiffnesses, a relevant ingredient which may also come into play is the difference in their diffusion coefficients $D$. Indeed, the time scale $t_0$ of the instability is inversely proportional to $D$ and a kinetic difference could also originate from this coefficient. However, considering the quantitative differences of the diffusion coefficients between these two orientations reported in Ref. 17, the inhibition of the instability on Si(111) cannot be explained by this effect. Indeed, the time constants for diffusion on Si(001) and Si(111) at 950°C are $1.5 \times 10^{-3}$ s\textsuperscript{20} and $10^{-6}$ s\textsuperscript{21} respectively, which testify a higher surface diffusion on Si(111) compared to Si(001).

Finally, other effects such as alloying are unlikely to have a strong enough influence on the instability dynamics.

As a conclusion, we studied the orientation dependence of the morphological ATG instability during MBE of thin SiGe strained films in coherent epitaxy on Si. While the strain-induced corrugation is fully developed on Si(001) substrates, its counterpart on Si(111) appears to be inhibited even after a 20 h long annealing. We revisited the basic ingredients of the elastic instability and concluded that the surface stiffness has a dramatic influence as it enforces a significant retardation of the dynamics. Considering the time necessary to obtain a large enough roughness, we find that the instability may be postponed over experimentally unreachable timescales due to the surface stiffness and we argue that this effect causes the absence of the morphological evolution on Si(111).

The authors thank R. Kern for fruitful discussions.
