Thousands of long noncoding RNAs (IncRNAs) have been found in vertebrate animals, a few of which have known biological roles. To better understand the genomics and features of IncRNAs in invertebrates, we used available RNA-seq, poly(A)-site, and ribosome-mapping data to identify IncRNAs of *Caenorhabditis elegans*. We found 170 long intervening ncRNAs (lincRNAs), which had single- or multiexonic structures that did not overlap protein-coding transcripts, and about sixty antisense IncRNAs (ancRNAs), which were complementary to protein-coding transcripts. Compared to protein-coding genes, the IncRNA genes tended to be expressed in a stage-dependent manner. Approximately 25% of the newly identified lincRNAs showed little signal for sequence conservation and mapped antisense to clusters of endogenous siRNAs, as would be expected if they serve as templates and targets for these siRNAs. The other 75% tended to be more conserved and included lincRNAs with intriguing expression and sequence features associating them with processes such as dauer formation, male identity, sperm formation, and interaction with sperm-specific mRNAs. Our study provides a glimpse into the IncRNA content of a nonvertebrate animal and a resource for future studies of IncRNA function.

[Supplemental material is available for this article.]

Since the discovery of *Xist*, a long noncoding RNA (IncRNA) required for mammalian X chromosome inactivation (Borsani et al. 1991; Brockdorff et al. 1992; Brown et al. 1992), thousands of other IncRNAs have been reported in mammals and other vertebrates (Okazaki et al. 2002; Numata et al. 2003; Carninci et al. 2005; Guttman et al. 2009; Gerstein et al. 2010; Guttman et al. 2010; Kim et al. 2010; Orom et al. 2010; Grabherr et al. 2011; Pauli et al. 2011b; Ulitsky et al. 2011; Y Wang et al. 2011). When considering their genomic origins relative to annotated protein-coding genes, most IncRNAs are classified either as long intervening ncRNAs (lincRNAs), which derive from loci that do not overlap the exons of protein-coding genes, or as antisense ncRNAs (ancRNAs), which derive from the opposite strand of the protein-coding gene such that they have potential to pair to the mature mRNA. lincRNAs are also called long intergenic RNAs, and ancRNAs are also called natural antisense transcripts (NATs). Most IncRNA gene models resemble those of protein-coding genes in terms of the CpG islands, multiexonic structures, and poly(A)-signals, but they have no more than chance potential to code for protein and are translated poorly from relatively short reading frames, if at all (Numata et al. 2003; Guttman et al. 2010; Ingolia et al. 2011).

Although for most lncRNAs, functions have not yet been investigated, some are known to play gene-regulatory roles or other biological roles in cells or during embryonic development (Goodrich and Kugel 2006; Mercer et al. 2009; Huarte and Rinn 2010; Koziol and Rinn 2011; Pauli et al. 2011a; Tsai et al. 2011). For example, *HOTAIR* is a 2.2-kb lincRNA that recruits the polycomb complex to modify the chromatin state of HOX genes to repress their transcription (Rinn et al. 2007; Gupta et al. 2010; Tsai et al. 2010), and *TP53COR1* (also known as lincRNA-p21) is induced by TP53 upon DNA damage or oncogenic stress and causes the widespread suppression of numerous genes by recruiting the repressor protein HNRNPK, thereby acting as a potential tumor suppressor (Huarte et al. 2010). Additional lincRNAs are also associated with transcriptional regulation (Martinian et al. 2007; Wang et al. 2008; Zhao et al. 2008), whereas Malat1 can regulate genes at the post-transcriptional level by titrating an SR protein that regulates alternative mRNA splicing (Ji et al. 2003; Tripathi et al. 2010). Other examples include the megamind and cyrano lincRNAs, which are conserved from human to fish and play important roles in embryonic development (Ulitsky et al. 2011).

Compared to most mRNAs, lincRNAs generally accumulate to lower levels, and although some have detectable sequence conservation, many have no more conservation than expected by chance, implying that a large subset of IncRNAs are either biochemical noise or play newly evolved, species-specific roles (Carninci et al. 2005; Guttman et al. 2010; Cabili et al. 2011; Ulitsky et al. 2011). However, some lincRNAs without detectable sequence conservation derive from syntenic loci and have conserved gene structure (conserved exon size and number), suggesting that the apparent lack of conservation might reflect technical difficulties, such as greater challenges in accurate sequence alignment (Ulitsky et al. 2011).

IncnRNAs are also found in invertebrates, as illustrated by the *roX1* and *roX2* lincRNAs, which are required for dosage compensation in flies (Larschan et al. 2011). In *Caenorhabditis elegans*, a subgroup of the modENCODE consortium carried out RNA-seq on poly(A)-selected RNA, which enabled annotation of 64,824 transcripts from 21,733 genes that would be expected to include some with little coding potential (Hillier et al. 2009; Gerstein et al. 2010). In parallel, using orthologous criteria (tiling array data, predicted RNA secondary structures, and sequence conservation), another subgroup of the consortium predicted ~7000 noncoding RNA (ncRNA) candidates, 1678 of which did not overlap with annotated protein-coding genes (Gerstein et al. 2010; Lu et al. 2010). However, we noticed that the overlap between these 1678 ncRNA candidates and the 64,824 transcripts identified by RNA-seq included only 24 transcripts, which is smaller than the chance expectation of 120 ± 8 (mean ± SD for 10 cohorts of length-matched
loci falling between protein-coding genes), implying that the confident identification of IncRNAs in *C. elegans* might benefit from additional analyses.

One potential function of noncoding transcripts is to serve as precursors or templates for the production of endogenous guide RNAs for RNAi or related silencing pathways. For example, the BIC proto- oncogene ncRNA was later reannotated as the primary transcript of the mammalian miR-155 miRNA (Lagos-Quintana et al. 2002). *C. elegans* has PIWI-interacting RNAs (21U-RNAs) and many endogenous small interfering RNAs (endo-siRNAs), including 22G-RNAs and 26G-RNAs (which tend to start with a G and be 22 and 26 nt long, respectively) (Ruby et al. 2006; Batista et al. 2008). The most abundant class of endo-siRNAs, 22G-RNAs, are produced by RRF-1 and EGO-1, RNA-dependent RNA polymerases (RDRPs) acting on template transcripts, and then become associated with worm-specific argonautes (WAGO proteins and CSR-1) (Ruby et al. 2006; Claycomb et al. 2009; Gu et al. 2009). CSR-1-associated 22G-RNAs target thousands of germ-line-specific genes, tend to map to the exons of those mRNAs, and are implicated in chromosome segregation (Claycomb et al. 2009). By contrast, WAGO-1-associated 22G-RNAs often map to both introns and exons of pre-mRNAs and have unknown biological roles (Gu et al. 2009). In addition, some 22G-RNAs map to clusters of loci lacking annotated transcripts. Because they did not correspond to known transcripts, such RNAs were initially annotated as a unique class of small-RNAs (tiny noncoding RNAs, or tncRNAs), distinct from endogenous siRNAs (Ambros et al. 2003). However, as high-throughput sequencing revealed their similarities to endo-siRNAs, tncRNAs were reclassified as siRNAs, with the presumption that they derive from ncRNA template transcripts that still needed to be identified (Ruby et al. 2006; Pak and Fire 2007).

In this study, we identify IncRNA genes, starting with a pipeline that constructs transcript annotations de novo by combining data from RNA-seq and poly(A)-site mapping and then removes those with detectable protein-coding potential or experimentally observed ribosome association. Hundreds of IncRNAs that have either single- or multiexonic transcript structures with poly(A) signals were found, thereby providing a glimpse into the IncRNA content of a nonvertebrate animal.

**Results**

**De novo gene annotation using multimodal transcriptome data**

We first developed a pipeline for global de novo annotation of transcripts from RNA-seq and poly(A)-site data sets. Because our focus was on IncRNAs, we chose not to consider information helpful for predicting protein-coding transcripts (such as sequence conservation, homology with known genes, codon usage, or coding potential), reasoning that by avoiding the consideration of this information we could use our accuracy for identifying previously annotated mRNAs to indicate accuracy for identifying IncRNAs.

Using TopHat, an alignment program that maps RNA-seq reads to putative exon junctions as well as genomic sequence (Trapnell et al. 2009), we mapped more than 1 billion reads (including 50 million exon-junction reads) from 25 non-strand-specific RNA-seq data sets (Gerstein et al. 2010; Lamm et al. 2011) and more than 80 million reads (including 5 million exon-junction reads) from 10 strand-specific RNA-seq data sets (Fig. 1A; Supplemental Table S1A,B; Lamm et al. 2011). To avoid false-positive exon-junction hits, we required that the inferred introns be ≥40 nt and ≤3058 nt, which would capture all but the shortest and longest 1% of introns within annotated protein-coding genes. Using the Cufflinks program (Trapnell et al. 2010), de novo gene annotations were constructed for non-strand-specific and strand-specific RNA-seq data sets, respectively (Fig. 1A). As expected, the annotations based on larger amounts of data (non-strand-specific RNA-seq) were more sensitive, whereas the annotations based on more informative reads (strand-specific RNA-seq) were more specific (Supplemental Table S1C), especially in instances of convergent overlapping transcripts, which are quite common in *C. elegans*, where they include a sixth of the mRNAs (Jan et al. 2011).

To maximize both sensitivity and specificity, we designed scripts that (1) used information from the strand-specific reads to correct the non-strand-specific annotations, systematically evaluating each exon for strand-specific support and for transitions in the strand supported (Supplemental Fig. S1A), (2) incorporated information from exon-junction hits that was not incorporated in the original annotations from either the strand-specific or non-strand-specific data (Supplemental Fig. S1B), (3) used poly(A) sites identified using 3P-seq (poly[A] position profiling by sequencing) (Jan et al. 2011) to assign 3’ ends of most transcripts (Supplemental Fig. S1B). The resulting 82,462 transcripts from 24,644 loci included 84.1% of the nucleotides falling within the RefSeq protein-coding transcripts (ce6), and the RefSeq protein-coding transcripts made up 66.3% of the nucleotides within the 82,462 transcripts (Supplemental Table S1C). These percentages did not perfectly reflect annotation sensitivity and specificity, in part because these RefSeq protein-coding transcripts were missing any IncRNAs that might be present in *C. elegans* as well as the 3’ UTRs of many protein-coding transcripts (Mangone et al. 2010; Jan et al. 2011). Moreover, based on observations in vertebrates, where IncRNAs tend to be expressed at levels lower than those of protein-coding transcripts (Guttman et al. 2010; Cabili et al. 2011; Ulltisky et al. 2011), the sensitivity for IncRNAs was expected to be lower than that of protein-coding transcripts (Supplemental Fig. S2). Nonetheless, the improvement of these percentages over those of our initial de novo annotations suggested even greater sensitivity than that achieved for the annotations from non-strand-specific data and even greater specificity than that achieved for the annotations from strand-specific data (Supplemental Table S1C).

The 82,462 transcript isoforms (including 3’ UTR isoforms) consisted of 78,940 multi-exon transcripts and 3521 single-exon transcripts, which together derived from 24,644 unique loci (Fig. 1A). Most of the loci overlapped with those annotated by modENCODE (Fig. 1B), as expected, because both sets of annotations were based largely on the same non-strand-specific RNA-seq and 3P-seq data sets (Gerstein et al. 2010). Nonetheless, our annotations included 3745 unique loci. In addition, 1347 modENCODE loci were not detected, presumably because we did not include EST data or the additional types of information useful for predicting protein-coding loci.

**Genome-wide identification of IncRNAs**

To identify IncRNAs, our 24,644 loci were filtered to remove those that overlapped the sense strand of annotated protein-coding genes, pseudogenes, ribosomal RNA, tRNA, miRNA, and other known classes of ncRNAs (Ce6 and Ensembl version 57). Of the 3291 loci (5029 transcript isoforms) that remained after this filtering, 1546 (2522 transcript isoforms) with ≥100 nt of antisense overlap with pre-mRNAs or other annotated transcripts were classified as ancRNA candidates, and the remaining 1745 loci (2507 transcript isoforms) were designated IncRNA candidates (Fig. 1A).
For each of these lncRNA candidates, coding potential was evaluated, removing those with (1) scores $\leq -1.0$ when using the coding potential calculation (CPC) program (Supplemental Fig. S3A; Jia et al. 2010), (2) marginal confidence in coding potential ($P \leq 0.01$) as evaluated using the RNAcode program (Washietl et al. 2011), or (3) evidence of ribosome association in experiments that sequenced RNA either sedimenting with polyribosomes (polyribosome reads/RNA-seq RPKM $\leq 0.1$) (Supplemental Fig. S3B; Lamm et al. 2011) or protected by ribosomes (ribosome RPKM/RNA-seq RPKM $\leq 0.1$) (Supplemental Fig. S3C; Stadler and Fire 2011). We also excluded loci that overlapped recently annotated protein-coding genes (through WormBase release WS231). This filtering retained 801 potential lincRNA loci (Fig. 1C) and 344 potential ancRNA loci (Fig. 1D). Further analysis using the 3P-seq data to identify transcripts with evidence of a poly(A) tail recovered 170 lincRNA loci, which were represented by 262 alternative splicing/3′-end isoforms, and 58 ancRNA loci, which were represented by 95 alternative splicing/3′-end isoforms (Fig. 1E; Supplemental Table S2). The lincRNA loci were named using the linc gene classifier (i.e., linc-1 through linc-170), and the ancRNA loci were named using the anr classifier (an acronym for ancRNA that is also the reverse of “RNA”). The search for lncRNA poly(A) sites included more genomic regions than did the previous analysis of UTRs (Jan et al. 2011) and, therefore, identified poly(A) sites that had not been previously recognized (Supplemental Fig. S4). The mean lengths of the lincRNAs and ancRNAs with assigned poly(A) sites were 830 and 756 nt, respectively, which were shorter than the mean length of mRNAs (~2.2 kb) (Supplemental Table S2A,B).

The potential lncRNAs with assigned poly(A) sites (Supplemental Table S2C,D) were carried forward as our set of C. elegans lncRNAs because they were the ones most confidently annotated as independent transcripts. Of the 170 lincRNA loci, 95 overlapped a modENCODE gene model (Gerstein et al. 2010) and nine overlapped one of the 1678 ncRNA candidates (Lu et al. 2010). Of the 58 ancRNA loci, 24 overlapped a modENCODE gene model (Gerstein et al. 2010). Although identified with less confidence, the potential lncRNAs without 3P-seq support (Supplemental Table S2E,F) are likely to include some interesting transcripts, including canonical lncRNAs that have poly(A) tails but lacked 3P-seq support because they are not highly expressed at the stages with 3P-seq data. Other potentially interesting transcripts, presumably including some enhancer-associated transcripts, might not be polyadenylated. One highly conserved noncoding RNA excluded because it lacked a poly(A) tail was the metazoan signal-recognition particle RNA (Supplemental Table S2E).

mRNA partners of ancRNAs

Of the 58 ancRNAs, 39 were fully embedded within pre-mRNA partners (14 fully within introns), 11 had divergent overlap with their pre-mRNA partner, four had convergent overlap, and four fully encompassed their pre-mRNA or ncRNA partner. About half of the mRNA partners were hypothetical genes without confirmed
Nam and Bartel

expression, which raised the possibility that many might not be authentic mRNAs (implying that the corresponding ncRNAs might eventually be reannotated as lincRNAs). For mRNA partners in each subgroup, we found no evidence for common functions (as measured using Gene Ontology enrichment). Expression analysis for each subgroup revealed that only convergent pairs tended to be anti-correlated with each other and that, for convergent pairs, more examples will be needed to establish statistical significance (mean \( r = -0.17 \), \( P = 0.16 \), one-sample t-test) (Supplemental Fig. S5).

Occasional trans-splicing of lincRNAs

Identifying transcript start sites (TSSs) is challenging in \( C. \) elegans because trans-splicing often replaces the 5' end of pre-mRNAs with a splice-leader sequence (Fig. 1F). Approximately 70% of mRNAs possess splice leaders at their 5' end, most of which have unknown TSSs. To examine whether lincRNAs also possess splice leaders, we looked for evidence of chimeric RNA-seq reads that did not map to the genome and instead had at least 12 nt of splice leader sequence (choosing from the 10 leaders most frequently observed for mRNA) fused to sequences in the 5' regions of lincRNAs and mRNAs (Fig. 1F). Of the 343,660 RNA-seq reads that contained the 3' part of a splice leader but did not match the genome, 87,194 were chimeric reads that resulted from trans-splicing near the 5' end (within –500 to 100 nt) of mRNAs for 20,587 unique RefSeq genes. This analysis captured 6624 unique junctions with at least two reads (Supplemental Table S3A). In contrast, only 52 chimeric reads capturing only 12 unique junctions with at least two reads (Supplemental Table S3B) represented trans-splicing to the 170 lincRNAs (within –500 to 100 nt of the 5' end inferred by RNA-seq reads). Even when compared to expression-matched mRNAs, the number of chimeric reads and unique trans-splicing junctions were more abundant for mRNAs than for lincRNAs (Fig. 1G).

Trans-splicing frequently serves to separate polycistronic pre-mRNAs into individual mRNAs. In \( C. \) elegans, >1000 openopons have been identified, each containing two to eight genes and accounting for 15% of all \( C. \) elegans genes (Spiegh et al. 1993; Blumenthal and Gleason 2003). Among the 170 lincRNA genes, three tandem clusters were found (Supplemental Table S4), each containing lincRNA genes within 1 kb of each other. For example, \( linc-41 \) is next to \( linc-21 \), with only 320 bp separating the two genes (Supplemental Fig. S6). The fraction of clustered lincRNA genes (1.8%) was much less than that of protein-coding genes, and none of corresponding lincRNAs were associated with the SL2 sequence, which is used for polycistronic pre-mRNAs (Spiegh et al. 1993). These observations suggest that lincRNA genes are less likely than protein-coding genes to have the operon-like transcript structure. Because trans-splicing tends to occur very close to the start codon, the splice leader is also thought to confer more efficient translation initiation (Blumenthal and Steward 1997; Lall et al. 2004). This role for the splice leader would help explain why trans-splicing is more frequent for mRNAs than for lincRNAs. Indeed, we found that for mRNAs, the AUG translational start codon was the codon most enriched in the 30 nt downstream from the junctions (adjusted \( P = 8 \times 10^{-5} \)), whereas for lincRNAs, other codons were enriched instead (CCG, adjusted \( P = 8.9 \times 10^{-4} \) and GAC, adjusted \( P = 0.012 \)) (Supplemental Table S3C). Taken together, our results show that some \( C. \) elegans lincRNA primary transcripts are trans-spliced, but for the few that are trans-spliced, the trans-splicing plays a role apart from separating polycistronic transcripts or enhancing translation initiation.

lincRNAs antisense to endo-siRNA clusters

When mapping published (Batista et al. 2008; Gu et al. 2009) and newly generated small-RNA sequencing data (Supplemental Table S5), we noticed that highly expressed endo-siRNAs often mapped antisense to lincRNAs (examples in Supplemental Fig. S7). Of the 170 lincRNAs, 46 were antisense to either 22G-RNAs (small-RNA RPKM ≥ 5) or 26G-RNAs (small-RNA RPKM ≥ 5) in at least one developmental stage (Supplemental Table S6; Supplemental Fig. S8A). This fraction of lincRNAs (27.1%) was comparable to that of protein-coding genes antisense to endo-siRNAs (32.1%). As observed for mRNAs, more highly expressed lincRNAs tended to map antisense to endo-siRNAs (Supplemental Table S6; Fig. 2A; Supplemental Fig. S8A). For example, 44% of 73 lincRNAs with mean RPKM ≥ 1 mapped antisense to 22G-RNAs (small-RNA RPKM ≥ 5) in L4 or adult stages (Fig. 2A), whereas only 9.3% of lincRNAs with mean RPKM < 1 mapped antisense to 22G-RNAs in the same stages (Supplemental Fig. S8A; Table 1).

Although, overall, lincRNAs resembled mRNAs in mapping antisense to endo-siRNAs, lincRNAs tended to map to some subclasses of endo-siRNAs more than to others. About 40% of both lincRNAs and mRNAs with RPKM ≥ 1 in adult mapped antisense to 22G-RNAs (\( P = 0.22 \), Fisher's exact test), whereas the fraction antisense to WAGO-1-associated 22G-RNAs was much higher for lincRNAs than for mRNAs (37.5% and 10.6%, respectively, \( P = 8 \times 10^{-8} \), Fisher's exact test) (Table 1). Moreover, 26% of 72 lincRNAs with mean RPKM ≥ 1 mapped antisense to 26G-RNAs (small-RNA RPKM ≥ 5) in either embryo or L4 stages—a fraction more than seven times higher than that of mRNAs (\( P < 1 \times 10^{-8} \)), which increases to 100 times higher when considering 26G-RNAs in the embryo stage (\( P < 10^{-26} \)) (Table 1).

Many of the endo-siRNAs that mapped to previously unannotated regions of the genome mapped antisense to our newly annotated lincRNAs. After grouping the 22G-RNAs mapping within 100 nt of each other into clusters and ranking the clusters by the number of 22G-RNA reads, we found that the first and seventh clusters mapped antisense to \( linc-22 \) and \( linc-29 \), respectively (Fig. 2B; Supplemental Fig. S7A). Three other clusters mapped antisense to pseudogenes, another class of ncRNA gene (Fig. 2B). A similar analysis of 26G-RNA clusters (grouping those mapping within 1000 nt of each other) found that five of the top 30 clusters mapped antisense to lincRNAs and that two mapped antisense to a pseudogene (Fig. 2C; Supplemental Fig. S7B). Moreover, three 22G-RNA and three 26G-RNA clusters mapped antisense to newly annotated transcripts that did not pass our cutoffs for lincRNA annotation because they satisfied only two of the three filtering criteria (Figs. 1C, 2B,C). Overall, the lincRNA annotations and other recent gene-annotation improvements (Gerstein et al. 2010) provided substantial insight into the origins of endo-siRNAs, with most of the siRNA clusters that previously mapped to unannotated regions now mapping antisense to newly annotated transcripts (Supplemental Fig. S8B,C). Of those clusters mapping predominantly (90% of reads) to one annotation, between 3% and 16% (depending on the stage) mapped antisense to lincRNAs, a 12- to 47-fold enrichment compared to mRNAs (\( P < 0.006 \) to \( < 10^{-14} \)) (Supplemental Fig. S8B,C).

In RNAi-treated \( C. \) elegans, target mRNAs are down-regulated at both the post-transcriptional and transcriptional levels (Montgomery et al. 1998). RNAi-mediated transcriptional repression occurs cotranscriptionally, whereby nuclear-localized siRNAs inhibit RNA polymerase II elongation and facilitate the establishment of histone H3 lysine 9 methylation (H3K9me3) (Guang et al.
2010; Burkhart et al. 2011; Gu et al. 2012). By analogy, the lincRNAs antisense to endo-siRNAs presumably template the production of the corresponding siRNAs, some of which recruit heterochromatin factors to silence regions from which they originate. Supporting this conjecture, genes for lincRNAs antisense to 22G-RNAs and 26G-RNAs tended to map to the ends of chromosomes, which have a higher density of the H3K9me3 heterochromatic mark (Supplemental Fig. S9A), and these genes had significantly more H3K9me3 signal compared to genes for other lincRNAs (Supplemental Fig. S9B). Moreover, the H3K9me3 signal at these lincRNAs depended on the nrde-2 nuclear RNAi pathway (Supplemental Fig. S9C).

**Sequence composition and conservation of nematode lincRNAs**

The A/U contents of both lincRNA and ancRNA sequences were comparable to that of sampled intergenic regions, falling between that of CDS/5' UTRs and that of 3' UTRs (Fig. 3A), as observed for zebrafish and mammalian lincRNAs (Ulitsky et al. 2011). No base-composition differences were observed between lincRNAs antisense to endo-siRNAs and other lincRNAs (Fig. 3B).

The extent of sequence similarity (E-value \(\leq 10^{-10}\)) between lincRNAs (22 out of 170, 12.9%) was much higher than between mRNAs (1.8 ± 1.6% for 10 random cohorts of 170 mRNAs, \(P < 1.0 \times 10^{-3}\), Fisher's exact test) (Supplemental Fig. S10), due in part to the increased presence of repeat elements in lincRNA sequences (50% of lincRNAs with a similar sequence among them harbored an annotated repeat element). The fraction of lincRNAs with repeat sequences (17.6%) was much greater than for mRNAs (2.5%, \(P < 10^{-15}\), Fisher's exact test) (Fig. 3C,D). Repeat elements that lincRNAs shared included helitron, satellite sequences, LINE elements, and transposable repeat elements.

To examine the overall conservation of nematode lincRNAs, we used the phastCons scores (Siepel et al. 2005), focusing on residues that were aligned in the whole-genome sequence alignments but did not map to annotated repeats. The fraction of lincRNA residues aligned in the whole-genome alignments was 31.7%, which was much smaller than those of mRNA CDS (88%) and 3' UTRs (55%) and comparable to those of mRNA introns (25%) and intergenic controls, termed control exons (27%) (Fig. 3E). We compared the conservation of exons and introns of lincRNA to those of length-matched exons and introns of protein-coding genes. The aligned lincRNA exons were more conserved than corresponding lincRNA introns but much less conserved than CDS exons and 3' UTRs, and about as conserved as mRNA introns.
and length-matched control exons (Fig. 3F). The conservation of lincRNAs was anti-correlated with the density of corresponding endo-siRNAs (Fig. 3G), such that lincRNAs without antisense 22G-RNAs (46.5% of 170 lincRNAs) were more conserved than both mRNA introns and control exons, whereas those with the most antisense 22G-RNAs (24.1%) were least conserved (Fig. 3EG). These results suggest the existence of at least two different subclasses of lincRNAs: nonconserved ones associated with endo-siRNAs and moderately conserved ones not associated with endo-siRNAs. Likewise, some protein-coding genes and pseudogenes to which certain classes of endo-siRNAs map appear particularly nonconserved (Fischer et al. 2011). The lower conservation of lincRNAs associated with endo-siRNAs is consistent with origins from heterochromatic regions, which are often poorly conserved.

Some vertebrate lincRNAs contain short conserved regions, which play important roles despite rapid sequence evolution elsewhere in the lincRNAs (Uliksy et al. 2011). We examined whole-genome sequence alignments (Siepel et al. 2005) to check whether nematode lincRNAs also have short evolutionarily conserved sequence elements. Of lincRNA exons that had any conserved element, only −30% had a conserved segment >50 nt (phastCons score ≥0.5), whereas, of CDS exons that had any conserved element, −60% had a conserved segment >50 nt (P < 1.0 × 10−3, KS-test) (Fig. 3H; Supplemental Fig. S11). Thus, as in vertebrates, the conserved lincRNAs tend to have shorter regions of conservation than do conserved mRNAs.

Developmental expression of nematode lincRNAs

In vertebrates, lincRNAs tend to be expressed in a development-specific manner (Cabili et al. 2011; Uliksy et al. 2011). To examine if this was also the case for C. elegans lincRNAs, we compared for each gene model the maximum expression among 10 developmental stages to the mean expression over the remaining nine stages (Fig. 4A; Supplemental Table S7A). By this metric, lincRNAs tended to be expressed more differentially than did mRNAs, with a median fold difference between maximum and mean RPKMs of 5.6 for lincRNAs, compared to 3.7 for mRNAs (P < 7 × 10−7, KS-test) (Fig. 4A). The most extreme example was linc-3, which had an RPKM of 1002 in the dauer stage, which was 10,000 times greater than the average of the nine other stages and conditions (Fig. 4A,B). Of the 46 unique lincRNAs with maximum RPKM ≥ 8, 20 had ratios exceeding 10, and linc-1 had the highest maximum RPKM, which exceeded 1360 in male-related stages (Supplemental Table S7A,B). The more specific expression of many lincRNAs might partly explain their lower overall expression levels.

To study coexpression of lincRNAs in specific conditions or developmental stages, we performed a CLICK clustering analysis (Sharan et al. 2003), based on Pearson correlation of z scores derived from expression distributions for each lincRNA. Four major coexpressed clusters were found, accounting for 24 embryo-specific, 41 early larval-specific, 49 sperm-specific, and 21 dauer-specific lincRNAs (Fig. 4C; Supplemental Table S7C–F). Using a similar approach, we also found one coexpressed cluster comprising 38 L3-specific ancRNAs (Supplemental Fig. S12; Supplemental Table S7G,H). As expected if some lincRNAs were templates of siRNAs, the sperm-specific lincRNAs were more frequently antisense to endo-siRNAs. Although five sperm-specific lincRNAs were transcribed from genes within 10 kb of each other, most lincRNAs in each expression cluster were from genes that were not close together (Supplemental Table S7C–F).

The expression relationships between two neighboring genes can correlate with their orientations with respect to each other, with tandem or divergent genes showing a greater tendency to be coexpressed (Korbel et al. 2004; Chen and Stein 2006; Kenschke et al. 2008; Chen et al. 2010; GZ Wang et al. 2011). We examined the extent to which lincRNA genes were coexpressed with their closest neighboring protein-coding gene (limiting the analysis to genes within 1 kb of each other, which excluded 74 of the 170 lincRNAs) (Supplemental Fig. S13). Expression of the lincRNA and nearest protein-coding gene tended to be correlated, especially for the gene pairs in tandem and divergent orientations (Fig. 4D). Longer-range correlations were also observed for large clusters of genes within 200-kb regions (Supplemental Table S8). For instance, within a 200-kb region centered on the dauer-specific linc-3 gene, for which expression peaked in the dauer-entry stage (Fig. 5A,B), the protein-coding genes also tended to be expressed in a dauer-specific manner, peaking after dauer entry (Fig. 5C). As a result, the expression correlations between linc-3 and each of the 59 genes in this larger region tended to be higher than that for 1000 cohorts of number-matched controls (mean r = 0.24, adjusted P < 4 × 10−7, one-sample t-test). This region included genes for serpentine receptors, which are seven trans-membrane G-coupled chemo-receptors thought to function in a dauer pheromone signaling pathway (Kim et al. 2009; McGrath et al. 2011). The functions of these coexpressed neighboring genes supported the idea that linc-3 might also play a role in dauer formation or maintenance. Although short- and longer-range correlations were observed

Table 1. lincRNAs antisense to endo-siRNAs (small-RNA RPKM ≥ 5) in L4 and adult stages

| lincRNA & mRNA antisense to endo-siRNAs | LincRNAs antisense to endo-siRNAs | LincRNAs antisense to endo-siRNAs | Difference between lincRNA & mRNA (P-value) |
|----------------------------------------|----------------------------------|----------------------------------|------------------------------------------|
| RNA-seq RPKM ≥ 1                      | RNA-seq RPKM ≥ 1                  | RNA-seq RPKM ≥ 1                  |                                           |
| lincRNAs                              | lincRNAs                         | lincRNAs                         |                                           |
| LincRNAs in L4                        | LincRNAs in adults                | LincRNAs in adults                |                                           |

When analyzing individual stages, the RNA-seq RPKM was determined for that stage. When analyzing multiple stages, mean RPKM was used. Differences in the fraction matching endo-siRNAs between lincRNAs and mRNAs (both RPKM ≥ 1) were tested for significance using the Fisher’s exact test.
between the expression of lincRNAs and neighboring protein-coding genes, the correlations did not significantly differ from those observed between two neighboring protein-coding genes (Fig. 4D). These results resembled those observed in vertebrates (Ulitsky et al. 2011) and suggested that, compared to protein-coding genes, the lincRNA genes were no more likely to be misannotated extensions of neighboring genes and no more likely to influence expression of their neighboring genes.

Expression correlation of a lincRNA and complementary mRNAs

Five lincRNAs had a long region significantly similar to the sense strand of an mRNA ($\geq 100$ nt, $E$-value $< 10^{-5}$) (Supplemental Table S9A), and one lincRNA had a long region significantly antisense to an mRNA ($\geq 100$ nt, $E$-value $< 10^{-5}$) (Supplemental Table S9B). Although these six unique lincRNAs might either derive from pseudogenes of protein-coding genes or simply share a common repeat element (Supplemental Table S9A,B), they nonetheless represented only 3.5% of our annotated lincRNAs, a much lower fraction than observed for mRNAs with homology with other mRNAs (19%).

Examination of shorter regions of homology identified 31 lincRNAs aligning antisense to one or more mRNAs ($E$-value $< 10^{-5}$), comprising 168 gene pairs (Supplemental Table S10A). This fraction (18.2%) was significantly higher than that observed for number- and length-matched mRNA sequences (10.3 ± 1.8%, comprising an average of 31 pairs for 100 cohorts of computational controls, $P < 0.021$, Fisher’s exact test). However, when excluding lincRNAs (and mRNA controls) associated with repeat elements, only 16 aligned antisense to one or more mRNAs, and the fraction of lincRNAs with antisense matches (11.4%) was not significantly higher than that for the controls (11.6%, $P = 0.43$). These results indicated that the tendency to map antisense to short regions of mRNAs occurred through repeat elements, raising the question as to whether it occurred by chance or has functional implications. Even after controlling for repeats, the number of the antisense pairs (78) was twice as high for the lincRNAs as for mRNA controls (30 ± 17), largely because a short conserved region of linc-55 mapped antisense to 37 members of a large gene family encoding major sperm proteins and their hypothetical
Figure 4. Developmental- and stage-specific expression of lincRNAs. (A) Differential expression of lincRNAs. For each lincRNA and mRNA, the maximum RPKM value from 10 distinct developmental stages (Supplemental Table S1B) is plotted relative to the mean value for the remaining nine stages. If the mean value was 0, a small value (0.1) was added to avoid the log 0 value error. For stages with multiple samples, the median value of RPKMs was used. The inset shows cumulative distributions of log2-scaled ratios of maximum and mean RPKMs for lincRNA and mRNAs. (B) Dauer-specific expression of linc-3. Plotted are the RPKM values of linc-3 in 10 distinct stages. (C) Four large lincRNA expression clusters over 35 different developmental stages/conditions (top key). Colored asterisks indicate lincRNA genes within 10 kb of each other. Within each cluster, lincRNAs are sorted based on their expression level (mean RPKM), with the expression level indicated at the far right. The five columns on the right show the abundance (RPKM) of endo-siRNAs mapping antisense to each lincRNA (bottom key). (D) Correlation between lincRNA expression and that of their closest protein-coding gene. Shown is the average correlation for pairs with the indicated relative orientations (tandem, convergent, and divergent), considering only pairs within 1 kb of each other. As a control, mean correlations were also calculated for number-matched cohorts of random pairs of lincRNA and protein-coding genes. For comparison, mean correlations were calculated for number-matched cohorts of protein-coding gene pairs. For both the controls and comparisons, the average correlation of 1000 cohorts is reported for each orientation, with error bars showing the 95% confident interval.
paralogs (Fig. 6). These 37- to 52-nt regions of complementarity did not trigger endo-siRNAs. Overall, there was not a strong tendency for the expression of \textit{linc-55} or that of other lincRNAs with short regions of antisense complementarity to be anti-correlated with expression of their complementary mRNAs (Supplemental Table S10B).

**Discussion**

Methods for annotating lncRNAs are improving but are still far from perfect. As with lists from previous efforts in other species, our lists of \textit{C. elegans} ancRNAs and lincRNAs contain some very confident annotations and others that are less confident, primarily because they are not as well supported in the RNA-seq and 3P-seq data sets. The lower expression of lincRNAs compared to mRNAs has been used as evidence that they represent transcriptional noise or lack biological significance (Birney et al. 2007; Clark et al. 2011). However, the lower expression level might be due in part to their tissue-, stage-, and condition-specific expression patterns. Although we identified hundreds of lincRNAs in \textit{C. elegans}, we suspect that, with additional data, more lincRNAs will be confidently and accurately annotated in this species. These will include many genes that lacked exon-junction reads for one of their introns and thus were missed because the unannotated intron disrupted connectivity to a 3P-supported poly(A) site. In fact, even after considering lincRNAs and the available RNA-seq data, some clusters of endo-siRNAs and 8436 poly(A) sites (13.2%) identified using 3P-seq remain unassociated with known gene models. Other lncRNAs that remain unannotated include those with tandem overlap with protein-coding genes, as we excluded any candidates with even a single nucleotide of sense overlap because of the difficulties in distinguishing between authentic lincRNAs and alternative 5' or 3' extensions of known genes.

Other potential sources of false-negatives in our lncRNA data sets were the stringent criteria used to filter out potential protein-coding genes. Most notable was our use of RNAcode (Washietl et al. 2011), an algorithm that compares the rates of synonymous and nonsynonymous changes in whole-genome alignments to find
evidence of conserved protein-coding potential. Because RNAcode can evaluate only sequences that are aligned to other genomes, any lncRNAs genes mistakenly flagged and removed by the algorithm would be conserved in other species and thus would be among those most attractive for experimental follow-up. When applying less stringent criteria (CPC < 0 and no consideration of RNAcode and polyribosome association), an additional 133 lincRNA and 102 ancRNA candidates were retained (Supplemental Table S11).

Another source of false negatives might have been our exclusion of annotated protein-coding genes, particularly the hypothetical protein-coding genes. With this in mind, we tested the coding potential of 19,907 RefSeq protein-coding genes. Eleven passed our criteria for annotation as potential lincRNAs, and three of these also had 3P-seq-supported poly(A) sites (Supplemental Table S12). Nine had been classified as hypothetical proteins, and the other two were fungus- and bacteria-response genes. None had evidence for trans-splicing.

Although more lncRNAs will undoubtedly be found, the identification of lincRNAs and ancRNAs in C. elegans, with initial characterization of their evolution, genomics, and expression, provides a starting point for the study of lincRNA biology in an invertebrate animal. For some of the lincRNAs, expression or sequence features already associate them with processes such as dauer formation, male identity, sperm formation, and interaction with sperm-specific mRNAs. The study of these and other newly identified lincRNAs in C. elegans, with its established tools for rapid molecular genetic analyses, can now contribute to the understanding of the fascinating biology and mechanisms of these enigmatic transcripts.

**Methods**

**Data sources**

C. elegans genome assembly ce6 was used throughout the study. For comparison to our de novo gene annotations and to analyze endo-siRNA clusters, NCBI RefSeq gene annotations (ce6, version Oct-3-2010) were used. To filter de novo transcripts overlapping with annotated genes, NCBI RefSeq gene annotations (ce6, version Oct-3-2010), Ensembl annotations (version 57), and WormBase annotations (WS231) were used. To find repeat loci, we used UCSC repeat-masking data (Jurka 2000). All public RNA-seq data, polyribosome data, and ribosome profiling data were obtained from NCBI SRA (SRA003622 and SRA049309) and NCBI GEO (GSE22410 and GSE19414). 3P-seq data were taken from NCBI GEO (GSE24924). Small-RNA data were from previous studies, supplemented with newly acquired 5' monophosphate-independent sequencing of small RNAs from L4 and adult stages (Supplemental Table S5). Small-RNA sequencing was as described (Batista et al. 2008).

**Analysis of start codon enrichment**

The frequencies of the AUG start codon in the 30 nt downstream from trans-splicing sites of lincRNAs and mRNAs were compared to the background frequency observed within ~500 to 100 nt of the trans-splicing sites. The P-values were estimated by the hypergeometric test and adjusted by the Bonferroni correction.

**Expression correlation analysis**

To measure expression correlation between mRNAs and lincRNAs and among lincRNAs, we used RPKM values across 35 different developmental stages/conditions. To measure expression correlation among ancRNAs, we used RPKM values across 10 different stages that have strand-specific RNA-seq data.

**Sequence conservation analysis**

For the comparisons, we excluded intronic regions and 3' UTRs with sense overlap with an RNAcode region (P ≤ 0.01) because lincRNAs did not include RNAcode regions, and then randomly sampled 1000 exons and introns, and 500 3' UTRs from genes. The introns were limited to those that did not overlap with any exons of alternative isoforms. For control exons, we considered intergenic regions, again excluding any region with sense overlap with an RNAcode region, and then randomly sampled 500 exon-length-matched regions. For each region, we calculated the mean phastCons score (Siepel et al. 2005), which was then adjusted by the fraction of residues aligned in multiple-genome alignments.

**Additional bioinformatic analysis**

To find sequence-similar lincRNAs and mRNAs and to find antisense-matching mRNAs, NCBI BLASTN was used with the param-
eter “blastn –e 0.001 –K 1” and E-value cutoff of $10^{-10}$ for lincRNA, $10^{-5}$ for miRNAs, and $10^{-3}$ for antisense-matching mRNAs.

Data access

The data discussed in this publication have been deposited in the NCBI Gene Expression Omnibus (GEO) (http://www.ncbi.nlm.nih.gov/geo/) (Edgar et al. 2002) and are accessible through GEO Series accession number GSE36394 (http://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE36394).

Acknowledgments

We thank Wendy Johnston for technical support, the WI genome technology core for sequencing, David Garcia and Vikram Agarwal for helpful discussions and inspection of our loci, which helped eliminate false positives from our final lists of lincRNA and anncRNA loci. This work was supported by a grant (GM067031) from the NIH. D.B. is an Investigator of the Howard Hughes Medical Institute.
