CASE REPORT

Tubercular Pyomyositis: An Uncommon Presentation of Extrapulmonary Tuberculosis

Satish Swain¹, Akansha Didwania², Manish Soneja³

ABSTRACT

*Background:* Tubercular pyomyositis is a rare entity in immunocompetent individuals, and involvement of head and neck region is very uncommon. It usually presents as diffuse swelling with some tenderness and other constitutional symptoms of tuberculosis (like a low-grade fever, loss of appetite, and weight loss). It can also mimic other entities like a pyogenic abscess, malignancy (sarcoma), benign soft tissue tumors, cervical lymphadenitis, and hematoma; which can pose a diagnostic challenge.

*Case description:* We here present a case of a 22-year-old male who came with complaints of neck swelling with low-grade fever and weight loss for about a month duration. A detailed clinical history and examination helped us to narrow down the differential. Finally, radiological imaging and microbiological test aided in clinching the diagnosis and helping with further management. The patient was diagnosed with tubercular pyomyositis of cervical muscles and was successfully treated with first-line anti-tubercular therapy.

*Keywords:* Extrapulmonary tuberculosis, Infectious disease, Musculoskeletal infection.

The Journal of Medical Sciences (2021): 10.5005/jp-journals-10045-00164

BACKGROUND

Tuberculosis is now a global concern and a serious threat to public health around the globe, especially the underdeveloped and developing nations. Tubercular pyomyositis is an uncommon form of extrapulmonary tuberculosis involving skeletal muscles. It has varied clinical presentations which sometimes can pose a diagnostic challenge in clinical practice.

CASE DESCRIPTION

A 22-year-old male, non-smoker and with no prior comorbidities presented with a swelling over the left side of the neck which was insidious in onset and gradually progressing in size over the last 1.5 months. The patient also has a history of intermittent low-grade fever (99.9–100°F) with weight loss of over 7 kg over past 2–3 months. On local examination, there was a mildly tender, non-pulsatile, swelling roughly measuring 4 cm by 5 cm (Fig. 1A) over the left posterior triangle of the neck with mild erythema over the overlying skin. There was no palpable lymphadenopathy noted, while the examination of the respiratory, cardiovascular, abdominal, and nervous systems was unremarkable. Routine hematological and biochemical parameters were within normal limits, apart from an elevated erythrocytic sedimentation rate (ESR) of 55 mm/hour. The chest radiograph was also normal. The patient also tested negative for human immunodeficiency virus (HIV), hepatitis B (HBsAg), and hepatitis C (Anti-HCV). An initial ultrasonography (USG) examination was done which revealed a well-defined predominately hypoechoic lesion. Later, a contrast-enhanced computed tomography (CECT) scan of the neck was done to further characterize the swelling which showed an enhancing collection in left paravertebral muscles of the neck without any boney involvement (Figs 1B and C). The collection was aspirated under ultrasound guidance and was sent for bacterial, tubercular, and fungal stains and cultures. The bacterial and fungal workup (Gram stain, KOH stain) did not yield anything but Ziehl–Neelsen (ZN) stain showed acid-fast bacilli. Gene Xpert™ of the same also detected *Mycobacterium tuberculosis* with rifampicin sensitivity.

The patient was started on weight-based first-line anti-tubercular therapy [Isoniazid (H), Rifampicin (R), Pyrazinamide (Z), Ethambutol (E)] with a final diagnosis of cervical paravertebral pyomyositis of tubercular etiology. The patient is currently following up with us in the infectious disease clinic of our institute and is doing well.

DISCUSSION

Pyomyositis is a purulent infection of skeletal muscle, usually with abscess formation and most commonly caused by *Staphylococcus* (90% cases), but tubercular pyomyositis is a very uncommon entity.¹ In a study by Wang et al., out of 1,153 culture-positive tuberculosis, 1.8% had tuberculous myositis and none of them had involvement of head and neck muscles.² Other cases of tubercular pyomyositis are limited to case reports and mostly in a backdrop of an immunocompromised condition (immunosuppressive therapy, corticosteroids, retroviral disease, or renal failure).³ ⁴ Skeletal muscles are usually resistant to infection from tubercular bacilli, although the exact mechanisms are not known, it has been implicated to high lactic acid concentration, poor oxygen content, and absence of reticuloendothelial cells and lymphatic tissue in

Mycobacterium reaches skeletal muscles via extension from adjacent structures (like bone, synovial membrane, or tendon sheaths), direct inoculation (needles, trauma), or via lymphatic or hematogenous seeding from a distant site. The clinical picture in bacterial pyomyositis is divided into three stages: invasive (variable fever, painful muscle swelling, and minimal systemic symptoms), suppurative (high spiky fever, with more severe systemic symptoms and classical signs of abscess), and late (bacteremia, septicemia, septic shock, and metastatic complications). But these various clinical stages of and classical signs (like high-grade fever, muscle tenderness, and leukocytosis) pyogenic pyomyositis may not be apparent in tubercular etiology, which may pose a diagnostic challenge. This entity may mimic other clinical conditions like a pyogenic abscess, malignancy (sarcoma), benign soft tissue tumors, cervical lymphadenitis, and hematoma; so it becomes important to distinguish between them. Imaging studies (like USG, CT scan, and MRI) are important in making a diagnosis along with microbiological evaluations like stains, culture, and molecular methods (Gene Xpert™, PCR, etc.). Management comprise anti-tubercular therapy and surgery. Response to standard anti-tubercular therapy (category I ATT) HRZE for 2 months (induction phase) followed by HRE for 4 months (continuation phase) has a good response. Drug resistance tubercular pyomyositis as detected by Gene Xpert™, or line probe assay or culture will require longer therapy with second line anti-tubercular agents. Surgical drainage or aspiration is needed for management as well as for etiological diagnosis (cytopathological or microbiological).

**Clinical Significance and Conclusion**

Tubercular pyomyositis is a rare entity and a form of extrapulmonary tuberculosis. This may mimic other clinical conditions which may pose a diagnostic challenge. Radiological and microbiological diagnostic aid as described is very helpful in reaching the diagnosis. Finally, this disease entity has an excellent response to anti-tubercular therapy.
