Cardiac-specific Hexokinase 2 Overexpression Attenuates Hypertrophy by Increasing Pentose Phosphate Pathway Flux

Kyle S. McCommis, PhD; Diana L. Douglas, BS; Maike Krenz, MD; Christopher P. Baines, PhD

Background—The enzyme hexokinase-2 (HK2) phosphorylates glucose, which is the initiating step in virtually all glucose utilization pathways. Cardiac hypertrophy is associated with a switch towards increased glucose metabolism and decreased fatty acid metabolism. Recent evidence suggests that the increased glucose utilization is compensatory to the down-regulated fatty acid metabolism during hypertrophy and is, in fact, beneficial. Therefore, we hypothesized that increasing glucose utilization by HK2 overexpression would decrease cardiac hypertrophy.

Methods and Results—Mice with cardiac-specific HK2 overexpression displayed decreased hypertrophy in response to isoproterenol. Neonatal rat ventricular myocytes (NRVMs) infected with an HK2 adenovirus similarly displayed decreased hypertrophy in response to phenylephrine. Hypertrophy increased reactive oxygen species (ROS) levels, which were attenuated by HK2 overexpression, thereby decreasing NRVM hypertrophy and death. HK2 appears to modulate ROS via the pentose phosphate pathway, as inhibition of glucose-6-phosphate dehydrogenase with dehydroepiandrosterone decreased the ability of HK2 to diminish ROS and hypertrophy.

Conclusions—These results suggest that HK2 attenuates cardiac hypertrophy by decreasing ROS accumulation via increased pentose phosphate pathway flux. (J Am Heart Assoc. 2013;2:e000355 doi: 10.1161/JAHA.113.000355)

Key Words: glucose • hexokinase • hypertrophy • oxidative stress

Under normal situations, the heart relies heavily on fatty acid oxidation for its energy metabolism. However, during cardiac hypertrophy there is a switch to increased glucose utilization and decreased fatty acid metabolism. Glucose metabolism is initiated by cellular glucose uptake mediated by glucose transporters (GLUT), and glucose phosphorylation by a hexokinase (HK) to form glucose-6-phosphate. There are 4 mammalian HK isozymes that exist, with both HK1 and HK2 expressed in the heart. As HK2 expression is dynamically regulated by factors such as insulin and hypoxia, HK2 receives most of the attention as the predominant muscle HK. In addition to the kinase function of HK1 or HK2, both enzymes contain a hydrophobic region of 21 amino acids in their N-termini, which allows for association with the voltage-dependent anion channel (VDAC) on the outer mitochondrial membrane. This mitochondrial localization protects cells against death; this protection has mainly been attributed to a reduction in reactive oxygen species (ROS).

It is still debated whether the increase in glucose utilization during hypertrophy is an integral pathologic process. However, genetic models mostly argue that altered fatty acid metabolism is the driver of hypertrophy, and that increased glucose utilization is compensatory. For example, mice with cardiac-specific overexpression of peroxisome proliferator-activated receptor α (PPARα) demonstrate increased fatty acid metabolism, decreased glucose metabolism, and hypertrophied hearts compared with wildtype littermates. Deletion of PPAR-gamma coactivator 1α (PGC1α) increases hypertrophy and accelerates heart failure after pressure overload. Cardiac-specific overexpression of the GLUT1 transporter attenuated cardiac hypertrophy and improved survival after pressure overload. Antithetically, cardiac-specific deletion of the GLUT4 transporter spontaneously results in hypertrophied hearts. Regarding HK2, transverse aortic constriction-induced hypertrophy is associated with increased HK2 protein, an effect abolished in PGC1β-deficient
animals, whereas hearts from mice heterozygous for HK2 deletion have exacerbated cardiac hypertrophy after pressure overload. It was suggested that decreased HK2 expression decreases mitochondrial HK2, and increases ROS production due to mitochondrial permeability transition. Thus, these studies suggest that increasing glucose metabolism is likely a compensatory mechanism during hypertrophy.

Little is known about how increased glucose metabolism decreases cardiac hypertrophy. While glycolysis is considered the preferred route for glucose, other glucose utilization pathways consist of glycogen formation, the pentose phosphate pathway, and the hexosamine biosynthetic pathway. Importantly, phosphorylation of glucose by HK is the initiating step in all of these pathways. While glycogen does not appear to be altered during hypertrophy, flux through the pentose phosphate pathway and the hexosamine biosynthetic pathway increase during hypertrophy.

We therefore hypothesized that mice with cardiac-specific overexpression of HK2 would demonstrate decreased hypertrophy in response to chronic isoproterenol infusion. Indeed, HK2 overexpression did result in attenuated cardiac and cardiomyocyte hypertrophy in response to isoproterenol. HK2 overexpression also protected against isoproterenol-induced cardiomyocyte death. Overexpression of HK2 also decreased hypertrophy in cultured neonatal rat ventricular myocytes (NRVMs) treated with phenylephrine. Hypertrophy was associated with an increase in ROS accumulation, which was attenuated by HK2. HK2 overexpression increased glucose-6-phosphate dehydrogenase (G6PDH) activity within the pentose phosphate pathway, and inhibition of G6PDH blocked the ability of HK2 to attenuate ROS and hypertrophy. Taken together, these results support that HK2 overexpression is anti-hypertrophic due to increased glucose shuttling to the pentose phosphate pathway and reduction of ROS accumulation.

**Methods**

Animals were handled as approved by the University of Missouri Animal Care and Usage Committee in accordance with the Guidelines for the Care and Use of Laboratory Animals published by the National Institutes of Health.

**HK2 Transgenic Mice and Isoproterenol Infusion**

The cDNA for mouse HK2 was inserted into the α-myosin heavy chain (αMHC) promoter cassette and injected into fertilized FVB/N oocytes. Mice were maintained in a pure FVB/N background. Transgenic (TG) mice were identified by PCR. Both male and female mice were used and nontransgenic (NTG) littermates were used as controls. Chronic isoproterenol infusion (60 mg/kg per day for 14 days) was administered by implantation of mini-osmotic pump (Alzet) into 2- to 3-month-old mice under isoflurane anesthesia (1.2% to 1.8%, 0.6 L flow of O₂). Vehicle-treated mice were implanted with pumps to perfuse 0.9% saline.

**Echocardiography**

Echocardiograms were performed under isoflurane anesthesia (1.2% to 1.8%, 0.6 L flow of O₂) using a GE Vivid 7 ultrasound system (GE Healthcare) with a 12-mHz transducer. The echocardiographer was blinded to the treatment group. M-mode echocardiography was performed using the parasternal short-axis view of the left ventricle. Images were captured digitally and 6 consecutive cardiac cycles were measured and averaged for each animal.

**Histological Assessments**

Mice underwent deep inhalation anesthesia (2% to 3% isoflurane) and hearts were perfused through the apex with 4% paraformaldehyde in PBS containing 25 mmol/L KCl and 5% dextrose to stop hearts in end diastole. Hearts were then frozen in OTC and sectioned by microtome. Sections were stained with fluorescently labeled wheat germ agglutinin (WGA) or Gomori’s Trichrome. For the WGA labeling, 20 cells per field for a total of 10 fields were planimetered using NIH ImageJ. Sections were also stained for terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) utilizing a cell death detection kit (Roche).

**qRT-PCR Gene Expression Analysis**

RNA was extracted from mouse ventricles with TRizol (Invitrogen) for first-strand DNA synthesis (Superscript III First-Strand Synthesis System; Invitrogen). Quantitative reverse transcription-polymerase chain reaction (qRT-PCR) was performed using a Bio-Rad cycler with Sybr green intercalating dye (Takara SYBR Universal ProbeLibrary). Primer sequences were obtained from Roche’s Universal ProbeLibrary.

**Mitochondrial Isolation and Measurement of Mitochondrial Respiration**

For subcellular fractionation experiments, mouse hearts were subfractionated by differential centrifugation as previously described. Mitochondrial respiration was assessed by a Clark type electrode (Qubit) using Vernier LoggerPro software. Isolated mitochondria (125 μg) were suspended in buffer consisting of 150 mmol/L KCl, 5 mmol/L KH₂PO₄, 10 mmol/L Tris pH 7.4, 2.5 mmol/L MgCl₂, and 5 mmol/L glutamate/malate or 5 mmol/L succinate to obtain State2 respiration. Then 200 μmol/L ADP was added to initiate State3 respiration.
HK2 Attenuates Cardiac Hypertrophy
McCommis et al

Western Blotting Analysis

Mouse tissue or cell culture lysates were solubilized in lysis buffer containing 150 mmol/L NaCl, 10 mmol/L Tris (pH 7.4), 1 mmol/L EDTA, and 1% Triton-X100. Samples were sonicated and then centrifuged at 17 000 g for 10 minutes to remove insoluble debris. Protein concentration was measured by the Bradford method. Proteins were resolved on 10% SDS/PAGE gels, transferred onto PVDF membranes, and blocked with 10% milk in TBS-T. The membranes were then immuno-blotted using the following commercially available antibodies: anti-HK2, anti-HK1, anti-O-GlcNAcylation, and anti-VDAC (Abcam); anti-LDH (Santa Cruz); and anti-GAPDH (Millipore). Membranes were then incubated with the appropriate alkaline phosphatase-linked secondary antibody (Santa Cruz Biotechnology) and visualized by enhanced chemiluminescence (Amersham Biosciences).

HK2 Activity Assay

HK enzymatic activity was measured as described previously. Total HK, HK1, and HK2 activity were measured simultaneously, by means of HK2 denaturation at 45°C as formerly described. Briefly, total cytosolic and mitochondrial lysates were divided into 2 aliquots, 1 kept on ice and 1 put into a 45°C water bath for 1 hour to denature HK2. At the end of the denaturing step, hexokinase activity was determined in both aliquots by measuring glucose-6-phosphate formation coupled to NADPH formation spectrophotometrically at 340 nm. The assay buffer consisted of 100 mmol/L Tris-HCl pH 8.0, 10 mmol/L glucose, 0.4 mmol/L NADP⁺, 10 mmol/L MgCl₂, 5 mmol/L ATP, and 0.15 U of G6PDH. Activity was normalized to protein concentration as measured by the Bradford method.

Mitochondrial Swelling

Mitochondria were isolated as described above and resuspended in swelling buffer (150 mmol/L KCl, 5 mmol/L KH₂PO₄, 10 mmol/L Tris pH 7.4) to a final concentration of 0.25 mg/mL. De-energized mitochondria received no substrate, and 5 mmol/L glutamate/malate was added to the buffer to energize mitochondria. Mitochondrial swelling, an index of permeability transition, was induced by the addition of 250 μmol/L CaCl₂ or 100 μmol/L CaCl₂ for de-energized and energized mitochondria, respectively, and absorbance was measured spectrophotometrically at 520 nm.

Isolation and Culture of Rat Ventricular Myocytes

Neonatal rat ventricular myocytes (NRVMs) were isolated as previously described. Briefly, 1- to 3-day-old Sprague-Dawley rat pup heart ventricles were digested with trypsin and then collagenase according to the manufacturer’s instructions (Worthington). Isolated cells were plated on uncoated polystyrene dishes to remove cardiac fibroblasts, and then plated onto gelatin-coated dishes. Cells were maintained in M199 medium supplemented with 10% BGS for 24 hours, then serum-free M199 for the duration of experimentation. Hypertrophy was induced by treatment with 25 μmol/L phenylephrine (PE) or 2 μmol/L Angiotensin-II for a period of 48 hours. Glucose-6-phosphate dehydrogenase (G6PDH) activity was inhibited by treatment with 25 μmol/L dehydroepiandrosterone (DHEA) for 48 hours, concurrent with the hypertrophic drug treatment.

Creation and Infection of HK2 Adenovirus

Replication-deficient adenoviruses for β-galactosidase and mouse HK2 were generated using the AdEasy adenoviral system (Stratagene). NRVMs were infected with adenovirus at a multiplicity of infection of 100 plaque-forming units, and cultured for 24 hours before experimentation.

siRNA Transfection

NRVMs were transfected with 100 nmol/L of either a non-targeting control siRNA or an HK2-targeting siRNA pool (Dharmacon siGENOME Cat: M-051128-01) using Lipofectamine RNAiMax. Cells were transfected 48 hours before experimentation.

Measurement of NRVM Cell Area

For cell surface area determination, NRVMs were immunostained for tropomyosin (Sigma) and all cardiomyocytes in each random field were planimetered using NIH ImageJ to obtain 1 average per field. Data from ≥4 independent isolates with ≥4 random fields per group were summarized.

Measurement of ROS Accumulation

ROS was measured in NRVMs by staining with 1 μmol/L 2′,7′-dichlorofluorescein (DCF) (Invitrogen) in Hank’s buffered saline solution for 30 minutes. Cells were then washed with HBSS and imaged on a fluorescence microscope (Olympus IX51). Average DCF fluorescence per cell was determined with NIH ImageJ.

Measurement of NRVM Cell Death

NRVMs were treated with 50 μmol/L H₂O₂ for 1 hour, and then costained with Sytox Green (Invitrogen) to label dead cell nuclei and bis-benzimide to label all cell nuclei. Cells were then imaged on a fluorescence microscope and the percentage of dead cells was determined with NIH ImageJ.
**Glutathione Assay**

Reduced glutathione (GSH) levels were determined in cardiac and cultured myocyte lysates using a commercially available luciferase-based assay from Promega. Levels were then corrected for the protein concentration of each sample.

**G6PDH Activity Assay**

The enzymatic activity of G6PDH was measured as performed previously. Briefly, 100 µL of whole cell lysates were added to a cuvette with 900 µL of buffer (50 mmol/L Tris, 1 mmol/L MgCl₂, and 100 µmol/L NADP⁺, pH 8.1). Enzyme activity was measured by increase in absorbance at 340 nm, due to the conversion of NADP⁺ to NADPH, which is formed by both G6PDH and 6-phosphogluconate dehydrogenase (6PGDH) in the pentose phosphate pathway. Thus, 2 reactions were measured for each sample, 1 containing substrates for both G6PDH and 6PGDH (total dehydrogenase activity) and 1 reaction with substrate only for 6PGDH. G6PDH activity was then calculated by subtracting the 6PGDH activity from the total dehydrogenase activity. Substrate concentrations were 200 µmol/L glucose-6-phosphate and 200 µmol/L 6-phosphogluconate. Activity was normalized to protein concentration as measured by the Bradford method.

**Statistical Analysis**

All data are expressed as mean±SEM. Statistical significance was determined between 2 groups by an unpaired Student’s t test or between multiple groups with 1-way ANOVA followed by Scheffe’s post-hoc test. A P value <0.05 was considered significant.

**Results**

**Characterization of αMHC-HK2 Mice**

Cardiac-specific HK2 overexpression was performed by cloning the mouse HK2 cDNA into the αMHC promoter cassette. TG mouse hearts displayed ~3-fold increased HK2 expression compared to NTG littermates (Figure 1A and 1B). Total HK activity and HK2-specific activity were accordingly increased in HK2 TG mice (Figure 1C). Importantly, neither HK1 expression nor HK1 activity was altered by HK2 overexpression (Figure 1A and 1C). TG hearts were normal in appearance and displayed HW/BW ratios similar to NTG littermates (Figure 1D and 1E). Moreover, fractional shortening, ejection fraction, and chamber size were not different in the TG hearts when compared to the NTG controls (Table).

As HK2 can be localized to both the cytosol and mitochondria, we subfractionated NTG and TG hearts into cytosolic and mitochondrial fractions to assess the localization of the overexpressed HK2. Surprisingly, the majority of the overexpressed HK2 was found in the cytosolic fraction (Figure 2A and 2B). However, there was a small but significant increase in mitochondrial HK2 expression as well (Figure 2A and 2B). Total HK and HK2 activity were correspondingly increased mainly in the cytosolic fraction (Figure 2C), but also in the mitochondrial fraction (Figure 2D). Oxygen consumption was then measured in isolated cardiac mitochondria to assess functional differences. TG heart mitochondria exhibited a significant reduction in State3 respiration when stimulated with complex I substrates (glutamate/malate), but not with complex II substrate succinate (Figure 2E).
To determine whether mitochondrial permeability transition was inhibited in the TG mice, heart mitochondria were isolated and subjected to mitochondrial swelling induced by calcium. Despite a small yet significant HK2 overexpression on the mitochondria (Figure 2A and 2B), αMHC-HK2 hearts showed no protection against mitochondrial swelling under either de-energized (Figure 2F and 2H) or energized (Figure 2G and 2H) conditions.

αMHC-HK2 Mice Display Decreased Cardiac Hypertrophy in Response to Isoproterenol

We next investigated the effects of HK2 overexpression on the hypertrophic response. Isoproterenol infusion resulted in increased heart size (Figure 3A), but not body weight (data not shown), which significantly increased the HW/BW ratio (Figure 3B). HK2 overexpression attenuated the hypertrophic response to isoproterenol (Figure 3A and 3B). Wheat-germ agglutinin staining of LV heart sections indicated increased cardiomyocyte cross-sectional area with isoproterenol, and HK2 overexpression decreased this response (Figure 3C and 3D). Cardiomyocyte cross-sectional area trends were similar for septal wall cardiomyocytes, however, RV cardiomyocytes showed only ~15% increase in cell size with isoproterenol and HK2 overexpression had no effect (data not shown).

We then assessed the effects of HK2 overexpression on cardiomyocyte survival and cardiac function after isoproterenol infusion. In general, there were no signs of heart failure induced by the isoproterenol infusion. LV ejection fraction and fractional shortening remained normal with isoproterenol, and was unaltered by HK2 overexpression (Table). Overt fibrosis was not seen in either group as well (data not shown). Isoproterenol infusion did result in a small, yet significant increase in cardiomyocyte apoptosis, as measured by TUNEL staining of heart sections, and HK2 overexpression attenuated this increase in cardiomyocyte death (Figure 3E). Altogether, these results suggest that isoproterenol infusion induces cardiac hypertrophy, but not heart failure, and that HK2 overexpression reduces the cardiomyocyte hypertrophy.

Isoproterenol infusion also increased transcripts for ANP, BNP, and βMHC, common markers of the “fetal gene program” (Figure 3F through 3H). As HK2 overexpression limited hypertrophy, it was expected that the αMHC-HK2 hearts would exhibit decreased transcripts for these markers. In fact, HK2 overexpression resulted in non-significantly increased ANP, BNP, and βMHC transcript expression (Figure 3F through 3H). However, these transcripts were also slightly elevated in vehicle-treated TG mice compared to NTG littermates. Increased levels of these “hypertrophy” markers have also been shown in other models of increased glucose utilization.34

Table. Echocardiographic Data From NTG and HK2 TG Mice Treated With Isoproterenol

|                   | Vehicle | Isoproterenol |
|-------------------|---------|---------------|
|                   | NTG     | HK2 TG        |
| LVEDD, mm         | 3.34±0.07 | 3.30±0.09     |
| LVEDD, mm         | 2.06±0.08 | 1.98±0.07     |
| FS, %             | 38.6±1.2  | 40.1±1.2      |
| EF, %             | 75.5±1.3  | 77.2±1.2      |
| HR, bpm           | 404±23   | 368±19        |
| EF                 | 75.5±1.3  | 77.2±1.2      |
| FS                 | 38.6±1.2  | 40.1±1.2      |
| LVEDD              | 3.34±0.07 | 3.30±0.09     |
| LVEDD              | 2.06±0.08 | 1.98±0.07     |
| FS                 | 38.6±1.2  | 40.1±1.2      |
| EF                 | 75.5±1.3  | 77.2±1.2      |
| HR                 | 404±23   | 368±19        |

EF indicates ejection fraction; FS, fractional shortening; HK2, hexokinase-2; HR, heart rate; LVEDD, left-ventricular end diastolic dimension; LVESD, left-ventricular end systolic dimension; NTG, non-transgenic; TG, transgenic.

Overexpression of HK2 in vitro Attenuates Cardiomyocyte Hypertrophy

To better study the mechanisms of HK2’s anti-hypertrophic effect, we wanted to recapitulate our in vivo findings in a cell culture system. NRVMs were infected with either control β-galactosidase adenovirus or a mouse HK2 adenovirus (Figure 4A and 4B), and treated with phenylephrine (PE) to induce hypertrophy. PE (25 μmol/L) resulted in a 37% increase in NRVM area, and HK2 overexpression reduced this hypertrophic response to only 16% (Figure 4C and 4D). To confirm that this was not specific to PE we also tested angiotensin-II (AngII). AngII (2 μmol/L) increased NRVM area by 27%, while HK2 overexpression limited the AngII-induced hypertrophy to only 10% (Figure 4E). These results confirm our in vivo findings in that HK2 overexpression attenuates cardiomyocyte hypertrophy. We also investigated the effect of reduced HK2 expression by transfecting NRVMs with a HK2 siRNA, which reduced HK2 protein expression 60%, but did not affect HK1 (Figure 5A and 5B). In agreement with our HK2 overexpression results, decreased HK2 expression led to significantly increased NRVM hypertrophy in response to 25 μmol/L PE (Figure 5C and 5D). These results further indicate that HK2 expression modulates cardiomyocyte hypertrophy.
HK2 Modulates ROS During Cardiomyocyte Hypertrophy

As ROS levels have been shown to be elevated during hypertrophy, and HK2 is known to be protective against ROS-induced death, we decided to investigate whether HK2 expression affected ROS levels during cardiomyocyte hypertrophy. PE treatment increased NRVM ROS levels by 65% as measured by DCF fluorescence (Figure 6A). HK2 overexpression reduced the ROS accumulation during hypertrophy, to an increase of only 24% (Figure 6A). HK2 depletion by siRNA exacerbated the accumulation of ROS during PE-induced hypertrophy (Figure 6B). This modulation of ROS levels during hypertrophy led us to question whether HK2 could decrease generalized oxidative stress; therefore we measured ROS levels in NRVMs overexpressing HK2 after treatment with 50 μmol/L...
H$_2$O$_2$. ROS levels were increased nearly 3-fold with H$_2$O$_2$ treatment, and HK2 overexpression significantly reduced this ROS accumulation (Figure 6C). HK2 overexpression also significantly reduced H$_2$O$_2$-induced NRVM death (Figure 6D). These results suggest that HK2 expression mediates ROS levels during cardiomyocyte hypertrophy and can protect against ROS-induced cardiomyocyte death.

**HK2 Modulates ROS via the Pentose Phosphate Pathway**

Lastly, we wanted to determine how HK2 controlled ROS levels during cardiomyocyte hypertrophy. One possible connection between glucose utilization and ROS is the pentose phosphate pathway. The initial step in this pathway is the conversion of glucose-6-phosphate into 6-phosphogluconolactone by G6PDH, which involves the reduction of NADP$^+$ to NADPH. NADPH can then be utilized to reduce glutathione and control ROS levels.$^{38}$ We therefore decided to test whether HK2 overexpression was controlling ROS levels by increasing flux through the pentose phosphate pathway. One of the end points of the pentose phosphate pathway is the reduction of glutathione. Consistent with increased flux we found that GSH levels were significantly increased in both HK2 TG hearts and HK2-overexpressing NRVMs compared to the respective controls (Figure 6E and 6F). We next treated

---

**Figure 3.** HK2 overexpression attenuates cardiac hypertrophy. B, Gravimetric analysis of heart weight/body weight ratio (HW/BW) for Vehicle- or ISO-treated NTG and TG mice (n=10 to 12). D, Representative wheat-germ agglutinin (WGA) images from left-ventricular (LV) sections of vehicle- or ISO-treated NTG and TG mouse hearts. D, LV cardiomyocyte cross-sectional area measured from WGA images as in (C) (n=4 to 6). E, Myocyte apoptosis, as determined by TUNEL staining, in vehicle- or ISO-treated NTG and TG mouse hearts (n=4 to 6). F through H, mRNA expression measured by qRT-PCR for (F), atrial natriuretic peptide (ANP), (G), B-type natriuretic peptide (BNP), and (H), β-Myosin heavy chain (βMHC) in vehicle- or ISO-treated NTG and TG mouse hearts. The 18s ribosomal subunit was used as loading control (n=6). Error bars represent SEM with *P<0.05 vs Vehicle and †P<0.05 vs NTG. HK2 indicates hexokinase-2; NTG, non-transgenic; qRT-PCR, quantitative reverse transcription-polymerase chain reaction; SEM, standard error of the mean; TG, transgenic; TUNEL, terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling.
NRVMs with dehydroepiandrosterone (DHEA), an inhibitor of G6PDH flux.
DHEA (25 μmol/L) treatment significantly decreased G6PDH activity by 55% (Figure 6G). HK2 overexpression resulted in significantly increased G6PDH activity (27% increase); however, DHEA maintained the ability to inhibit G6PDH activity with HK2 overexpression (Figure 6G). Similar to what was shown before, HK2 overexpression attenuated the increase in ROS accumulation induced by PE in vehicle treated NRVMs; however, DHEA cotreatment abolished the ability of HK2 to decrease ROS accumulation (Figure 6H). DHEA treatment also blocked the ability of HK2 to attenuate the PE-induced increase in cardiomyocyte size (Figure 6I). Together, these results suggest that HK2 overexpression attenuates ROS levels and hypertrophy by increasing glucose flux through the pentose phosphate pathway.

Discussion
Cardiac hypertrophy is characterized by a transition into the “fetal metabolic program”, involving decreased fatty acid metabolism and increased glucose utilization. Recent evidence from genetic models suggests that altered fatty acid metabolism is the driving force of pathologic hypertrophy, and increased glucose utilization may be a beneficial compensation. Therefore, we hypothesized that a mouse model of increased cardiac HK2 expression would result in a decrease in hypertrophy in response to chronic β-adrenergic stimulation. Indeed, αMHC-HK2 mice displayed decreased cardiac and cardiomyocyte hypertrophy in response to isoproterenol. HK2 overexpression also attenuated the hypertrophic response in vitro in NRVMs treated with PE or AngII. Oppositely, HK2 depletion by treatment of NRVMs with a HK2 siRNA exacerbated PE-induced hypertrophy. These results are in full agreement with most other studies investigating cardiac hypertrophy in models of altered glucose utilization. Cardiac-specific deletion of the GLUT4 transporter was shown to induce cardiac hypertrophy at basal conditions.20 Antithetically, cardiac-specific GLUT1 overexpression was shown to decrease hypertrophy, attenuate the transition to heart failure, and increase survival in response to pressure overload.19 Cardiac-specific PPARα overexpression has also been shown to increase fatty acid metabolism, decrease glucose utilization, and result in cardiac hypertrophy at basal conditions.17 Most recently, Hk2 heterozygous mice were shown to have increased hypertrophy and exacerbated heart failure in response to pressure overload.22 We also found that HK2 overexpression could reduce the TUNEL staining associated with isoproterenol-induced hypertrophy, suggesting that HK2 may also have anti-apoptotic properties in this context.

Figure 4. HK2 overexpression decreases cardiomyocyte hypertrophy in vitro. Journal of the American Heart Association
context. We also found that HK2 could attenuate oxidant-induced necrosis in NRVMs. These data are consistent with previous studies demonstrating that reduced HK2 levels enhanced pressure-overload- and ischemia/reperfusion-induced myocyte apoptosis, and overexpression of HK2 in NRVMs protects against oxidative-stress-induced death.

ROS levels have been shown to increase during hypertrophy, where they are thought to mediate the hypertrophic response by activating pro-hypertrophic signaling enzymes such as Ca²⁺/Calmodulin-dependent kinase, calcineurin/NFAT, and mitogen-activated protein kinase pathways. HK2 is known to be protective against ROS-induced death. Consistent with these data we found that treatment of NRVMs with PE resulted in increased ROS accumulation, and HK2 overexpression attenuated this increase in ROS levels. Conversely, HK2 knockdown further increased the ROS accumulation during PE-induced hypertrophy. The increased hypertrophy observed with decreased HK2 expression was suggested to be due to increased ROS accumulation as a result of mitochondrial permeability transition. Indeed mitochondrial permeability transition has been reported to contribute to aging-related hypertrophy, and overexpression of the mitochondrial pore subunit cyclophilin-D induces hypertrophy. However, isolated mitochondria from αMHC-HK2 hearts showed no difference in mitochondrial swelling experiments, suggesting that inhibition of permeability transition may not play a role in the anti-oxidant and anti-hypertrophic effects of HK2. We cannot fully rule out a mitochondrial mechanism, as there is a small but significant increase in HK2 mitochondrial expression in our overexpression model. Nevertheless, the much greater increase in HK2 expression in the cytosolic fraction in our model leads us to surmise that the anti-oxidant effect of HK2 is likely due to a more cytosolic or glucose utilization-based mechanism, rather than a mitochondrial mechanism.

We investigated how HK2 reduced ROS levels, and tested the theory that increased HK2 expression could increase pentose phosphate pathway flux, leading to reduced ROS. The pentose phosphate pathway is important for the formation of NADPH reducing equivalents that are necessary for glutathione peroxidase activity and production of reduced glutathione. Glucose-6-phosphate, the product of the reaction catalyzed by HK2, is the substrate for the initial reaction of the pentose phosphate pathway performed by G6PDH. Increased G6PDH

DOI: 10.1161/JAHA.113.000355
activity, and increased pentose phosphate pathway flux have been observed during cardiac hypertrophy. Genetic models of altered pentose phosphate pathway activity also suggest a prominent connection between this pathway and hypertrophy. Mice that are deficient in G6PDH develop hypertrophy and display increased hypertrophy after myocardial infarction or pressure overload. In the present study, DHEA treatment was utilized to decrease G6PDH activity by ≈55%. This level of inhibition did not result in significantly increased ROS accumulation or cardiomyocyte hypertrophy. However, inhibition of G6PDH did abolish the beneficial effects of HK2 overexpression against α-adrenergic stimulation-induced ROS production and cardiomyocyte hypertrophy. Interestingly, our ≈3-fold HK2

Figure 6. HK2 modulates reactive oxygen species (ROS) levels by increasing pentose phosphate pathway flux. A, Mean ROS levels as measured by 2′,7′-di-chlorofluorescein (DCF) fluorescence in AdβGal- and AdHK2-infected NRVMs treated with either vehicle or 25 μmol/L phenylephrine for 48 hours (n=4). B, Mean ROS levels as measured by DCF fluorescence in CONsi- and HK2-transfected NRVM treated with either vehicle or 25 μmol/L phenylephrine for 48 hours (n=4). C, Mean ROS levels as measured by DCF fluorescence in AdβGal- and AdHK2-infected NRVMs treated with vehicle or 50 μmol/L H2O2 for 1 hour (n=4). D, Cell death, as measured by Sytox Green, in AdβGal- and AdHK2-infected NRVMs treated with vehicle or 50 μmol/L H2O2 for 1 hour (n=6). E, Reduced glutathione (GSH) levels in cardiac lysates from NTG and TG mice (n=6). F, GSH levels in AdβGal- and AdHK2-infected NRVMs (n=3). G, Glucose-6-phosphate dehydrogenase (G6PDH) enzymatic activity in AdβGal- and AdHK2-infected NRVMs treated with vehicle or 25 μmol/L of the G6PDH inhibitor dehydroepiandrosterone (DHEA, n=4). H, Mean phenylephrine (PE)-induced increase in ROS levels in AdβGal- and AdHK2-infected NRVMs treated with vehicle or 25 μmol/L DHEA (n=4). I, Mean PE-induced increase in NRVM cell area in AdβGal- and AdHK2-infected NRVMs treated with vehicle or 25 μmol/L DHEA (n=5). Error bars represent SEM with *p<0.05 vs Vehicle and †p<0.05 vs AdβGal or CONsi. AdβGal indicates adenovirus expressing β-galactosidase; HK2, hexokinase-2; NRVM, neonatal rat ventricular myocytes; NTG, non-transgenic; SEM, standard error of the mean; TG, transgenic.

HK2 Attenuates Cardiac Hypertrophy McCommis et al

ORIGINAL RESEARCH
overexpression increased G6PDH activity ≈30%, which fits nicely with the estimation that 10% to 20% of glucose oxidation occurs through the pentose phosphate pathway.51 Consistent with this was our finding that GSH levels are elevated when HK2 is increased in cardiac myocytes. Thus, these results indicate that increased pentose phosphate pathway flux is an important component of the anti-hypertrophic effect of HK2.

Another possible fate of glucose-6-phosphate is the formation of O-linked β-N-acetylglucosamine residues, also known as protein GlcNAcylation, by the hexosamine biosynthetic pathway. Flux through this pathway also appears to be increased during cardiac hypertrophy as GlcNAc levels are increased in hypertrophied hearts.26,27 Hypertrophy also increases the expression of O-linked β-N-acetylglucosamine transferase, the enzyme responsible for adding GlcNAc residues to proteins, and deletion of this enzyme increases cardiomyocyte hypertrophy, apoptosis, and dysfunction.27 We did not thoroughly investigate the hexosamine biosynthetic pathway in this study; however, the wheat germ agglutinin used in this study is a marker of N-acetylglucosamine residues on cell plasma membranes. Analysis of the fluorescence intensity of these images does suggest that both HK2 overexpression and hypertrophy increase N-acetylglucosamine levels (Figure 7A), and blotting demonstrated a modest increase in protein O-GlcNAcylation in HK2 overexpressing hearts (Figure 7B). Therefore, increased protein O-GlcNAcylation could potentially be another mechanism decreasing both cardiomyocyte hypertrophy and apoptosis in our HK2 overexpression model. Further study is warranted to thoroughly investigate the response of the hexosamine biosynthetic pathway to altered HK2 expression.

A consistent finding was that overexpression of HK2 only partially abrogated the hypertrophy, increases in ROS, and cell death, whether in the mice or the cultured myocytes. This most likely stems from the fact that HK2 did not completely abolish the increases in ROS, which in turn would drive the hypertrophy and cell death. This could be due to the levels of HK2 and it is feasible that a greater level of HK2 could overcome this, totally prevent ROS production, and therefore fully restore a normal phenotype. However, it is likely that other ROS-independent pathways are also at play here. For example, the antioxidant tempol was only able to partially reverse the hypertrophy seen in GLUT4-deficient hearts.52 Similarly, n-acetylcysteine was only partially effective in blocking AngII-induced hypertrophy in vivo.53 Therefore, other HK2-insensitive signaling may contribute to the residual hypertrophy and cell death exhibited in the cells and mice.

To conclude, our results show that HK2 overexpression attenuates cardiomyocyte hypertrophy and death in response to adrenergic stimulation. Our in vitro studies suggest that HK2 modulates hypertrophy by controlling cellular ROS levels by increasing pentose phosphate pathway flux. Thus, therapeutic approaches to increase HK2 expression or pentose phosphate pathway flux may assist in the treatment of pathologic cardiac hypertrophy.
