(Dated: February 7, 2014)

We search for a spin-dependent P- and T-violating nucleon-nucleon interaction mediated by light pseudoscalar bosons such as axions or axion-like particles. We employed an ultra-sensitive low-field magnetometer based on the detection of free precession of co-located 3He and 129Xe nuclear spins using SQUIDs as low-noise magnetic flux detectors. The precession frequency shift in the presence of an unpolarized mass was measured to determine the coupling of pseudoscalar particles to the spin of the bound neutron. For boson masses between 2 µeV and 500 µeV (force ranges between 3·10^{-4} m - 10^{-1} m) we improved the laboratory upper bounds by up to 4 orders of magnitude.

PACS numbers: 06.30.Ft, 07.55.Ge, 11.30.Cp, 11.30.Er, 04.80.Cc, 32.30.Dx, 82.56.Na

Axions are light, pseudoscalar particles that arise in theories in which the Peccei-Quinn U(1) symmetry has been introduced to solve the strong CP problem [1]. They could have been created in early stages of the Universe being attractive candidates to the cold dark matter that could compose up to ∼1/3 of the ingredients of the Universe [2]. Several constraints from astrophysics, cosmology, and laboratory experiments have been applied in order to prove or rule out the existence of the axion, i.e., constrain the axions mass ma and/or its couplings. The mass range, in which axions are still likely to exist, could thus be narrowed down to a window reaching from µeV [3] up to some meV [4] (axion window).

Most axion searches look for the conversion of an axion of galactic [5], solar [6], or laboratory [7] origin into a photon in the presence of a static magnetic field. However, any axion or axion-like particle that couples with both scalar and pseudoscalar vertices to fundamental fermions would also mediate a parity and time-reversal symmetry-violating force between a fermion f and the spin of another fermion fr, which is parameterized by a Yukawa-type potential with range λ and a monopole-dipole coupling given by [8]:

\[ V_{sp}(\vec{r}) = \frac{\hbar^2 g_f^s g_p^e}{8\pi m_{f_r}} (\hat{\sigma} \cdot \hat{r}) \left( \frac{1}{\lambda r} + \frac{1}{r^2} \right) e^{-r/\lambda} \]  

(1)

\( \hat{\sigma} \) is the spin vector and λ is the range of the Yukawa-force with \( \lambda = \hbar/(m_a c) \). Thus, the entire axion window can be probed by searching for spin-dependent short-range forces in the range between 20 µm and 0.2 m. \( g_f^s \) and \( g_p^e \) are dimensionless scalar and pseudoscalar coupling constants which in our case correspond to the scalar coupling of an axion-like particle to a nucleon \( g_s^N = g_N^N \) and its pseudoscalar coupling to a polarized bound neutron \( (g_f^s = g_p^p) \). Accordingly, we have \( m_{f_r} = m_n \). \( \hat{r} \) is the unit distance vector from the bound neutron to the nucleon. The potential given by Eq. (1) effectively acts near the surface of a massive unpolarized sample as a pseudo-magnetic field and gives rise to a shift \( \Delta \nu_{sp} = 2 \cdot V_{sp}/\hbar \), e.g., in the precession frequency of nuclear spin-polarized gases (3He and 129Xe), which according to the Schmidt model [9] can be regarded as an effective probe of spin-polarized bound neutrons.

The potential \( V_{sp} \) is obtained by integration of \( V_{sp}(\vec{r}) \) from Eq. (1) over the volume of the massive unpolarized sample averaged over the volume of the polarized spin-sample, each having a cylindrical shape. Based on the analytical derivation of \( V_{sp,\infty} \) for disc-shaped spin- and matter samples with respective thicknesses D and d [10], we obtain

\[ V_{sp} = V_{sp,\infty} \cdot \eta(\lambda) = 2\pi N K \frac{\lambda^2}{D} \cdot e^{-\Delta x/\lambda} \times \left( 1 - e^{-D/\lambda} \right) \cdot \left( 1 - e^{-d/\lambda} \right) \cdot \eta(\lambda) \]  

(2)

\( \eta(\lambda) \) takes account for the finite size in transverse direction of our cylindrical samples and \( \Delta x \) represents the finite gap between them. Furthermore, \( \kappa = \hbar^2 g_N^N g_p^p/(8\pi \cdot m_a) \) and N is the nucleon number density of the unpolarized matter sample. \( \eta(\lambda) \) is determined numerically for our cylindrically shaped spin- and matter samples at "close"-position (see Fig.1).

Our experimental approach to search for non-magnetic, spin-dependent interactions is to use an ultra-sensitive low-field magnetometer based on detection of free spin precession of gaseous, nuclear polarized samples [11]. The Larmor frequencies of 3He and 129Xe in a guiding magnetic field B are given by \( \omega_{L,He(Xe)} = \gamma_{He(Xe)} / B \), with \( \gamma_{He(Xe)} \) being the gyromagnetic ratios of the respective gas species [12,13] with \( \gamma_{He}/\gamma_{Xe} = 2.75408159(20) \).

\( \eta(\lambda) \) can be expressed reasonably well by the fit function \( \eta(\lambda) = (1 + 27.8 \cdot \lambda^{3.34})/(1 + 234 \cdot \lambda^{1.31}) \).
The influence of the ambient magnetic field and its temporal fluctuations cancels in the difference of measured Larmor frequencies of the co-located spin samples

$$\Delta \omega = \omega_{He} - \frac{\gamma_{He}}{\gamma_{Xe}} \cdot \omega_{Xe}. \quad (3)$$

On a closer look, a resulting constant frequency shift $\Delta \omega_{lin}$, e.g., due to Earth’s rotation, is not compensated by co-magnetometry. That is discussed in [14], together with frequency shifts due to the generalized Ramsey-Bloch-Siegert shift. The latter ones are directly proportional to the particular net magnetization $A_{He(Xe)} \cdot e^{-t/T_{2,He(Xe)}}$ and also are included in the weighted frequency difference $\Delta \omega(t)$:

$$\Delta \omega(t) = \Delta \omega_{lin} + \epsilon_{He} \cdot A_{He} \cdot e^{-t/T_{2,He}} - \epsilon_{Xe} \cdot A_{Xe} \cdot e^{-t/T_{2,Xe}}. \quad (4)$$

Accordingly, its equivalent, the weighted phase difference $\Delta \Phi(t) = \Phi_{He}(t) - \frac{2 \pi}{\gamma_{Xe}} \Phi_{Xe}(t)$, is sensitive to a phase drift given by

$$\Delta \Phi(t) = \Phi_0 + \Delta \omega_{lin} \cdot t - \epsilon_{He} \cdot T_{2,He}^{-1} \cdot A_{He} \cdot e^{-t/T_{2,He}}$$
$$+ \epsilon_{Xe} \cdot T_{2,Xe}^{-1} \cdot A_{Xe} \cdot e^{-t/T_{2,Xe}}. \quad (5)$$

Due to the knowledge of these side effects, any anomalous frequency shifts generated by non-magnetic spin interactions, such as the quasist short range interaction, can be analyzed by looking at $\Delta \omega(t)$ and $\Delta \Phi(t)$, respectively. A sudden frequency change $\Delta \omega_{sp}$ stemming from the pseudoscalar Yukawa potential $V_{sp}(r)$ would occur at an instant $t = t_0$, e.g., by moving a massive matter sample close to the precessing nuclei. This would lead to an additional linear phase drift $\Delta \omega_{sp}$ at $t = t_0$. For further analysis, it is useful to develop Eq. (5) in a Taylor expansion of 5th order around $t_0$. The weighted phase difference $\Delta \Phi(t)$ can then be described by

$$\Delta \Phi(t') = a + b(t') \cdot t' + c \cdot t'^2 + d \cdot t'^3 + e \cdot t'^4 + f \cdot t'^5, \quad (6)$$

with $t' = t - t_0$. The coefficient of the linear term now reads

$$b(t') = \Delta \omega_{lin} + \Delta \omega_{sp}(t') + \epsilon_{He} \cdot A_{He}' - \epsilon_{Xe} \cdot A_{Xe}'. \quad (7)$$

Note that $\Delta \omega_{sp}(t') = 2 \pi \cdot \Delta \nu_{sp} \cdot \Theta(\pm t')$ is the only time dependent term in Eq. (7), so that a change $\delta \theta = \delta_{b} - \delta_{d} = 2 \pi \cdot \Delta \nu_{sp}$ of $b(t')$ at $t = t_0$ would directly indicate the existence of the short range interaction. With our special choice of $t' = t - t_0$, the linear coefficient of the Taylor expansion does not depend on $T_{2,He}$ and thus is insensitive to possible changes in $T_{2,He}$. The impact of the $T_{2,He}$-dependence of higher order terms on the determination of $b(t')$ is discussed in detail in section systematic uncertainties.

The experiments were performed inside the magnetically shielded room BMSR-2 at the Physikalisch-Technische Bundesanstalt Berlin (PTB) [15]. A homogeneous guiding magnetic field of about 350 nT was provided inside the shielded room by means of a square coil pair ($B_{y}$-coils) of edge length 1800 mm. A second square coil pair ($B_{x}$-coils) arranged perpendicular to the $B_{y}$-coils was used to manipulate the sample spins, e.g., $\pi/2$ spin flip by non-adiabatic switching [11]. The major components of the experimental setup within BMSR-2 are shown in Fig. 1. For the detection of spin precession we used a multi-channel low-$T_{2}$ DC-SQUID device [16][17]. The $^{3}$He/$^{129}$Xe nuclear spins were polarized outside the shielding by means of optical pumping. Low-relaxation cylindrical glass cells (GE180) were filled with the polarized gases and placed directly beneath the dewar as close as possible to the SQUID sensors. The SQUID sensors detect a sinusoidal change in magnetic flux due to the nuclear spin precession of the gas atoms. In order to obtain a high common mode rejection ratio, three first order gradiometric sensor combinations were used in order to suppress environmental disturbance fields like vibrational modes. Fig. 1 shows their positions with respect to...
to each other and with respect to the $^3\text{He}/^{129}\text{Xe}$ sample cell. The system noise of the SQUID gradiometer configurations was between 3 fT/√Hz and 10 fT/√Hz in the range of the $^3\text{He}/^{129}\text{Xe}$ spin-precession frequencies, i.e., 4 Hz < $\nu_1$ < 12 Hz, while typical signal amplitudes reached 10 pT for helium and 3 pT for xenon at the beginning of the spin precession cycle. Typically, the optimum conditions in terms of long transverse relaxation times ($T_2^\ast$) and high signal-to-noise ratio (SNR) were met at a gas mixture with pressures of $^3\text{He} : \text{Xe}$ (91% $^{129}\text{Xe}$) : $N_2 \approx (2 : 8 : 35)$ mbar. Nitrogen was added to suppress spin-rotation coupling in bound $\text{Xe-Xe}$ van der Waals molecules [18, 19]. As unpolarized matter sample we used a cylindrical BGO crystal (Bi$_4$(Ge$_2$)O$_{12}$, $\rho$=7.13 g/cm$^3$). BGO has a high nucleon number density, is a non-conductive material that shows low Johnson-Nyquist noise and is said to have an unusual magnetism-related behaviour in weak constant magnetic fields ($\chi_{\text{mag}} \approx 0$ ppm) [20–22]. For systematic checks, the BGO crystal could be placed left ($\mathcal{L}$) and right ($\mathcal{R}$) with respect to the $^3\text{He}/^{129}\text{Xe}$ sample cell (see Fig. 1). Since $V_{sp}(d) \propto \vec{\sigma} \cdot \vec{r}$, $\Delta \nu_{sp}$ changes its sign in going from $\mathcal{L}$ to $\mathcal{R}$. This has to be considered by averaging the $\mathcal{L}$ and $\mathcal{R}$ results. On the other hand, $\Delta \nu_{sp}$ drops out averaging $\mathcal{L}$ and $\mathcal{R}$ without sign change. In case of a non-zero spin-dependent axion fermion interaction, a shift $\Delta \nu_{sp}$ in the weighted frequency difference (Eq. 3) can be extracted from respective frequency measurements in "close" and "distant" position given by

$$\Delta \nu_{sp}^w = \frac{2V_{\Sigma,He}^2}{h} \left(1 - \frac{\gamma_{\text{He}}}{\gamma_{\text{Xe}}}\right), \quad (8)$$

assuming $V_{\Sigma,He} = V_{\Sigma,Xe} = V_{\Sigma,n} \equiv V_{\Sigma}$ (Schmidt model) and $V_{\Sigma,He}^2 \leq V_{\Sigma,Xe}^2$.

We performed 10 measurement runs lasting approximately 9 h each. For each measurement run, the BGO crystal was moved after $t_0 \approx 3$ h from "close to distant" position (c→d) or vice versa (d→c). The asymmetric timing takes account for the smaller SNR in the second measurement block due to the exponential damping ($T_2^\ast$) of the signal amplitude which was $T_{2,\text{He}}^\ast \approx 53$ h and $T_{2,\text{Xe}}^\ast \approx 5$ h, typically. By this measure, comparable statistics was obtained for both BGO positions.

As discussed in detail in [14], the data from each run were divided into sequential time intervals of $\tau = 3.2$ s. For each obtained sub-data set, a $\chi^2$-minimization was performed using an appropriate fit-function to extract the phases $\phi_{\text{He}}, \phi_{\text{Xe}}$ and the frequencies $\omega_{\text{He}}, \omega_{\text{Xe}}$ with the corresponding errors. In a further step, the accumulated phase $\Phi_{\mathcal{L}/\mathcal{R}}(t')$ was determined for each run in order to derive the weighted phase difference $\Delta \Phi(t')$. Then Eq. 6 was fitted simultaneously to the data set $\Delta \Phi(t')$ that was determined for the three gradiometers of each measurement run. From the resulting fit parameters $\bar{\tau}$, $\bar{b}_c$, $\bar{b}_d$, $\bar{\tau}$, $\bar{\eta}$, $\bar{\delta}$ and by use of Eqs. 7 and 8 the frequency shift $\Delta \nu_{sp}$ is then extracted from

$$\Delta \nu_{sp} = \frac{\bar{b}_c - \bar{b}_d}{2\pi \cdot \left(1 - \frac{\gamma_{\text{He}}}{\gamma_{\text{Xe}}}\right)} . \quad (9)$$

For 6 runs (# : 2, 3, 4, 5, 9, 10), the BGO crystal was positioned at $\mathcal{L}$ otherwise at $\mathcal{R}$. For all $\mathcal{L}$ runs, the results were multiplied by (-1): $\Delta \nu_{sp} = -\Delta \nu_{sp,\mathcal{L}}$. In Fig. 2a, values $\Delta \nu_{sp}$ for the individual runs are shown together with their correlated 1σ error [23]. From the calculation of the weighted mean, one gets $\Delta \nu_{sp} = (-2.9 \pm 2.3)$ nHz. As consistency check, we re-analysed our 2009 data, where we looked for a possible Lorentz-violating (LV) sidereal frequency modulation [14]. Since no mass was moved, $b_c = b_d$ should hold, using the fit-function of Eq. 6 and a hypothetical time $t_0 = 10800$ s. Fig. 2b shows the results $\Delta \nu_{\text{check}}$ for all 7 measurement runs together with their correlated 1σ errors. The weighted mean of the LV-data gives $\Delta \nu_{\text{check}} = (-1.4 \pm 3.4)$ nHz. The $\chi^2$/d.o.f of the data to their respective weighted means ($\Delta \nu_{sp}$, $\Delta \nu_{\text{check}}$) gives 2.29 and 2.38, indicating that the errors on the measured frequency shifts (Fig. 2a) are somewhat underestimated. In order to take this into account, the errors are scaled to obtain a $\chi^2$/d.o.f of one, as recommended, e.g., by [23] [24].

At the 95% C.L., our results for the measured frequency shifts are:

$$\Delta \nu_{sp} = (-2.9 \pm 6.9) \text{ nHz} \quad (10)$$

$$\Delta \nu_{\text{check}} = (-1.4 \pm 10.5) \text{ nHz} \quad (11)$$

The correlated errors are calculated as square root of the diagonal elements of the covariance matrix of the least $\chi^2$ fit-model of Eq. 6 with the proper statistical weights. The uncorrelated errors are about a factor of 30 smaller and not included in the error bars shown in Fig. 2a.
indicating that i) we find no evidence for a pseudoscalar short-range interaction mediated by axion-like particles and ii) the cross check analysis of our LV-data is compatible with zero within the error bars, as expected.

**Discussion of systematic uncertainties:**
The movement of the BGO-crystal can produce correlated effects that may mimic a pseudoscalar frequency shift or even compensate the effect we are looking for. Two effects caused by a non-zero magnetic susceptibility of the BGO have to be considered, by taking $\chi_{\text{mag}} = -19 \text{ ppm}$ which is the high field limit ($B > 0.1 \text{ T}$) [21].

a.) The BGO at "close" position slightly changes the magnetic field across the volume of the $^3\text{He}/^{129}\text{Xe}$ sample cell. This effect drops out to first order due to magnetometry. To second order, however, the difference in their molar masses leads to a difference ($\Delta z$) in their center of masses (barometric formula) which is $\Delta z = 1.2 \cdot 10^{-7} \text{ m}$ for our cylindrical sample cell. This results in a frequency shift of $\Delta \nu_{\text{sys}} = \Delta z \cdot \frac{|\langle \partial B / \partial z \rangle|_{\text{ind}} \cdot \gamma_{\text{He}}}{2 \pi} \leq 0.03 \text{ nHz}$ for induced field gradients in the vertical direction of $|\langle \partial B / \partial z \rangle|_{\text{ind}} \leq 0.08 \text{ pT/cm}$. The field gradients were calculated using COMSOL Multiphysics, a finite element analysis software. Compared to the measured frequency shift (Eq. 10), this systematic effect is negligible.

b.) More serious is the fact that a change of the magnetic field gradient for the BGO also influences the movement of the BGO-crystal can produce correlated effects. The most accurate distinction between signal amplitudes with the BGO in "close" and "distant" position. The most accurate distinction between $T_2^*$ times of $^3\text{He}$ and $^{129}\text{Xe}$. The direct approach is to extract $T_2^*$ and thus $\Delta T_2^*$ via the exponential decay of the signal amplitudes with the BGO in "close" and "distant" position. The most accurate distinction between $T_2^*$ and $T_2^*$ was obtained through a fit to the amplitude ratio $A_{\text{He}}(t')/A_{\text{He}}(t')$ given by $f_{\text{fit}}(t') = W \cdot e^{-t'/T_{\text{eff}}}$ with $T_{\text{eff}} = T_{\text{He}}^* \cdot T_{\text{He}}^* / (T_{\text{He}}^* - T_{\text{He}}^*)$. According to [11, 25, 26], a relation between $\Delta T_{2, \text{He}}^*$, $\Delta T_{2, \text{He}}^*$, and $\Delta T_{\text{He}}^*$ can be derived

$$\frac{\Delta T_{\text{He}}^*}{(T_{\text{eff}}^*)^2} = -\frac{\Delta T_{2, \text{He}}^*}{(T_{2, \text{He}}^*)^2} + \frac{\Delta T_{2, \text{He}}^*}{(T_{2, \text{He}}^*)^2} \approx -0.5 \frac{\Delta T_{2, \text{He}}^*}{(T_{2, \text{He}}^*)^2} \quad (12)$$

by taking the respective diffusion coefficients of $^3\text{He}$ and $^{129}\text{Xe}$ in the gas mixture and using the approximation $\Theta_D / 2 = D / 2 \approx R = 30 \text{ mm}$ for our cylindrically shaped cell. We obtain an upper limit of $|\Delta T_{2, \text{He}}^*| < 160 \text{ s}$ for a possible $T_2^*$-change. From that the systematic frequency shift $\Delta \nu_{\text{sys}}^*$ on $b(t')$ due to the higher order terms of (Eq. 9) can be estimated to be

$$|\Delta \nu_{\text{sys}}^*| \leq \left| \frac{\Delta T_{2, \text{He}}^*}{(T_{2, \text{He}}^*)^2} \cdot \left( \frac{E_{\text{He}}^* - 1}{2 \cdot T_{2, \text{He}}^*} \right) \cdot \frac{1}{2} \right| \approx 0.1 \text{ nHz}. \quad (13)$$

Here we used Eq. 9 replacing $\bar{b}_c$ and $\bar{b}_d$ by the temporal means $2 \cdot \bar{b}_c \cdot \langle t' \rangle_{\nu}$ and $2 \cdot \bar{b}_d \cdot \langle t' \rangle_{\nu}$ of the quadratic term in Eq. 6 with $\tau_c(\nu) = \left\{ -\left(E_{\text{He}}^*/2 \right) / \left(T_{2, \text{He}}^* \right)^2 \right\}$ and $E_{\text{He}}^*(\nu) = \epsilon_{\text{He}}(\nu) \cdot A_{\text{He}}(\nu) \cdot T_{2, \text{He}}^*(\nu)$. Values for the respective $E_{\text{He}}^*(\nu)$ phase amplitudes were extracted from the fit function (Eq. 9) applied to the data and result to be $E_{\text{He}}^*(\nu) = 11.5 \text{ rad}$ and $E_{\text{He}}^*(\nu) = 0.1 \text{ rad}$. Finally, $\langle t' \rangle_{\nu}$ was taken to be $\langle t' \rangle_{\nu} \approx t_0 / 2$.

From Eq. 13 a conservative estimate of the systematic error can be made with $|\Delta \nu_{\text{sys}}^*| = \pm 0.2 \text{ nHz} \ (95\% \ C.L.)$, which brings us to the final result

$$\overline{\Delta \nu_{\text{sp}}} = (-2.9 \pm 6.9 \pm 0.2) \text{ nHz} \ (95\% \ C.L.) \quad (14)$$

for the measured pseudoscalar frequency shift.

From the total error $\delta(\overline{\Delta \nu_{\text{sp}}} = \pm 7.1 \text{ nHz}$ we can then derive exclusion bounds for $|g^N g^p_0|$ using Eq. 2 and $|\delta(\overline{\Delta \nu_{\text{sp}}})| \geq 2 \cdot V_2^*/h$ which are shown in Fig. 5.

We have substantially improved the bounds on a spin-dependent short-range interaction between polarized (bound) neutrons and unpolarized nucleons over most of the axion window, tightening existing constrains on axion-like particles heavier than 20 eV by up to four orders of magnitudes.

And there are clear strategies on how to improve our experimental sensitivity: i) Close contact of the spin system with the matter sample. For $\Delta x \approx 0 \text{ mm}$, our present measurement sensitivity will significantly increase for $\lambda < 10^{-3} \text{ m}$ (see Fig. 5). ii) Moving the spin/matter sample more frequently between its set positions (c$\leftrightarrow$d and/or L $\leftrightarrow$ R). This results in a different time structure for the linear term in the fit model of Eq. 6 such that the correlated error approaches the uncorrelated one. This was demonstrated in [13] already. iii) Magnetic susceptibility related artefacts have to be eliminated by taking zero-susceptibility matched matter samples ($\chi_{\text{mag}} \approx 0 \text{ ppm}$) as it is common practice in high resolution NMR spectroscopy [27].

This work was supported by the Deutsche Forschungsgemeinschaft (DFG) under contract number BA 3605/1-1 and the research center "Elementary Forces and Mathematical Foundations" (EMG) of the University in Mainz, and by PRISMA cluster of excellence at Mainz. We are grateful to our glass blower R. Jera for preparing the low relaxation glass cells from GE180.
