Abstract

We present a unified derivation of Bohmian methods that serves as a common starting point for the derivative propagation method (DPM), Bohmian mechanics with complex action (BOMCA) and the zero-velocity complex action method (ZEVCA). The unified derivation begins with the ansatz $\psi = e^{iS/\hbar}$ where the action, $S$, is taken to be complex and the quantum force is obtained by writing a hierarchy of equations of motion for the phase partial derivatives. We demonstrate how different choices of the trajectory velocity field yield different formulations such as DPM, BOMCA and ZEVCA. The new derivation is used for two purposes. First, it serves as a common basis for comparing the role of the quantum force in the DPM and BOMCA formulations. Second, we use the new derivation to show that superposing the contributions of real, crossing trajectories yields a nodal pattern essentially identical to that of the exact quantum wavefunction. The latter result suggests a promising new approach to deal with the challenging problem of nodes in Bohmian mechanics.

PACS numbers:
I. INTRODUCTION

The contrast between the inherent non-locality of quantum mechanics and the locality of classical mechanics has driven a decades long quest for a trajectory-based formulation of quantum theory that is exact. In the 1950's, David Bohm, building on earlier work by Madelung [1] and de Broglie [2], developed an exact formulation of quantum mechanics in which trajectories evolve in the presence of the usual Newtonian force plus an additional quantum force [3, 4]. Bohm’s formulation was originally developed as an interpretational tool, to recover a notion of causality in quantum mechanics. In 1999 Lopreore and Wyatt [5] demonstrated that the Bohmian formulation can also be used a numerical tool to do quantum calculations. This innovation has coincided well with the ongoing interest of the chemical physics community in finding effective numerical tools for performing multidimensional quantum calculations. The apparently local dynamics of the Bohmian trajectories suggest the possibility of computational advantages compared to fixed grid methods or direct-product basis set methods that scale exponentially with dimensionality. The Lopreore and Wyatt paper has motivated the development of a variety of new numerical approaches for implementing Bohmian mechanics [6, 7, 8, 9, 10, 11, 12]. Reference [13] gives an excellent account of the progress in Bohmian related formulations in recent years.

The Bohmian formulation has two main limitations that currently limit its usefulness as a numerical tool. First, note that the non-locality of quantum mechanics does not disappear in the Bohmian formulation—it manifests itself in the quantum force term, which needs to be calculated to propagate the quantum trajectories. The quantum force is very unstable numerically when the wavefunction is oscillatory. This is related to the second limitation: the quantum force diverges at nodes of the wavefunction resulting in the break down of the Bohmian formulation in the vicinity of nodes. Indeed, most of the new contributions to Bohmian methodology have been aimed at overcoming these two limitations of the Bohmian formulation.

Among the approaches that have been developed to deal with the calculation of the quantum force are the derivative propagation method (DPM) [14] and Bohmian mechanics with complex action (BOMCA) [15, 16]. The two approaches use a similar procedure writing a hierarchy of equations of motion for partial derivatives of the phase. The difference between the methods lies in the use of a complex action in BOMCA as opposed to a real amplitude.
and phase in DPM. This difference has far-reaching consequences that we explore in this paper.

In the first part of this publication we present a unified and compact derivation of Bohmian methods that serves as a common starting point for the DPM and BOMCA methods, and the Zero-Velocity Complex Action (ZEVCA) method. The derivation is similar to the derivation of BOMCA but it leaves the choice of the trajectory velocity field undetermined. We demonstrate how different choices of the velocity field yield different formulations, such as DPM, BOMCA and others. The unified derivation allows for ready comparison of DPM and BOMCA, and the role that the quantum force plays in both formulations. In the second part of this paper we use the new derivation to show that superposing the contributions of real, crossing trajectories yields an interference pattern. This contrasts with a cardinal principle of the exact Bohmian formulation, that trajectories are not allowed to cross in configuration space. However, since we are dealing with an approximation to Bohmian mechanics, the no-crossing role does not apply. Superposing the contribution from real crossing trajectories represents a promising new avenue for dealing with the challenging problem of nodes in Bohmian mechanics.

This paper is organized as follows. In section II we present the unified derivation. Section III is dedicated to several special cases of the derivation: ZEVCA (III A), BOMCA (III B) and DPM (III C). In Section IV we show how a variation of the derivation leads to an accurate description of interference and nodal patterns. Section V is a summary and concluding remarks.

II. UNIFIED DERIVATION OF BOHMIAN METHODS

We start by inserting the ansatz

\[ \psi(x, t) = \exp \left[ \frac{i}{\hbar} S(x, t) \right], \tag{2.1} \]

into the TDSE

\[ i\hbar \psi_t = -\frac{\hbar^2}{2m} \psi_{xx} + V(x, t) \psi, \tag{2.2} \]

where \( S(x, t) \) is a complex function, \( \hbar \) is Planck’s constant divided by \( 2\pi \), \( m \) is the mass of the particle and \( V(x, t) \) is the potential energy function. The subscripts denote partial
derivatives. The result is a quantum complex Hamilton-Jacobi (HJ) equation \[17, 18, 19\]

\[S_t + \frac{1}{2m}S_x^2 + V = \frac{i\hbar}{2m}S_{xx},\]  

(2.3)

where we recognize on the LHS a complex version of the classical HJ equation. On the RHS is an additional non-classical term that we refer to as the “complex quantum potential”. This term is different from the quantum potential in the conventional Bohmian formulation. The time-independent version of ansatz (2.1) is familiar as the starting point of the WKB approximation\[20, 21, 22\]. Equation (2.3) was derived by Pauli\[17\] as a first step in the WKB derivation. More recently, eq.(2.3) was rediscovered by Leacock and Padgett\[23\], who also reverted to a time-independent formulation to calculate eigenvalues. The equation has also been used by several other authors\[24, 25, 26\] as an analytical tool, but not as a constructive method to solve the TDSE with trajectories.

The classical HJ equation can be conveniently solved by integrating along trajectories that satisfy the classical equations of motion. From a mathematical point of view, these trajectories are the characteristics of the classical HJ equation. Here we use an analogous approach to solve the quantum complex HJ equation, by integrating along some family of trajectories. We define a family of trajectories by choosing a velocity field \(v(x, t)\), which can be done in an infinite number of ways. (As opposed to the classical case, the velocity field is not necessarily predetermined by the PDE we are trying to solve.) Solutions of

\[\frac{dx}{dt} = v(x, t)\]

(2.4)

determine trajectories, parametrized by their initial position \(x(0)\). The change of the phase along the trajectory is given by operating on \(S(x, t)\) with the Lagrangian time derivative

\[\frac{d}{dt} \equiv \frac{\partial}{\partial t} + \frac{dx}{dt} \frac{\partial}{\partial x} = \frac{\partial}{\partial t} + v \frac{\partial}{\partial x},\]

(2.5)

with the result

\[\frac{dS}{dt} = S_t + vS_x = \frac{i\hbar}{2m}S_{xx} - \frac{1}{2m}S_x^2 - V + vS_x,\]

(2.6)

where we have used eq.(2.3). The integration of eq.(2.6) requires \(S_x[x(t), t]\) and \(S_{xx}[x(t), t]\), i.e. the values of the first two spatial derivatives of \(S\) along the trajectory. Fortunately, it is possible to write equations describing the evolution of the spatial derivatives of \(S\). Writing

\[S_{n}[x(t), t] \equiv \frac{\partial^n S}{\partial x^n} \bigg|_{[x(t), t]},\]

(2.7)
and taking the \( n \)th spatial derivative of eq. (2.3), we have
\[
(S_t)_n + \frac{1}{2m} (S_t^2)_n + V_n = \frac{i\hbar}{2m} S_{n+2} .
\] (2.8)

Inserting the result in the definition of the Lagrangian time derivative of \( S_n \) gives
\[
\frac{dS_n}{dt} = (S_t)_n + \nu S_{n+1} = -\frac{1}{2m} (S_t^2)_n - V_n + \nu S_{n+1} + \frac{i\hbar}{2m} S_{n+2} .
\] (2.9)

From this procedure we obtain an infinite set of coupled equations describing the evolution of \( S \) and its spatial derivatives along a trajectory, namely eqs. (2.9) for \( n = 0, 1, 2, \ldots \). We note that evaluation of \( S_n \) requires knowledge of \( S_{n+2} \) and \( S_{n+1} \) (the latter through the term \( (S_t^2)_n = \sum_{j=0}^n \binom{n}{j} S_{j+1} S_{n-j+1} \)). The fact that evaluation of \( S_0 = S \) requires knowledge of \( S_2 = S_{xx} \) expresses the \textit{nonlocality} of the Schrödinger equation. However from a formal point of view, integration of the infinite hierarchy of eqs. (2.9) along the trajectories defined by eq. (2.4) can be regarded as a local method of solution of eq. (2.3) in the sense that information propagates along individual trajectories independently. This does not contradict the nonlocality of the Schrödinger equation, since not only is the value of \( S \) being propagated down a trajectory, but also all its spatial derivatives \( S_1, S_2, \ldots \) are being propagated.

A numerical approximation for solving eq. (2.3) can be obtained by truncating the set (2.9) at some \( n = N \), by setting \( S_{N+1} = S_{N+2} = 0 \). We summarize the equations of motion of the approximation:
\[
\frac{dx}{dt} = \nu[x(t), t],
\] (2.10)
\[
\frac{dS_n}{dt} = -\frac{1}{2m} (S_t^2)_n - V_n + \nu S_{n+1} + \frac{i\hbar}{2m} S_{n+2}; \quad n = 0, 1, \ldots, N,
\] (2.11)
\[
S_{N+1} = S_{N+2} = 0,
\] (2.12)

where we emphasize that the solution is given along an individual trajectory \( x(t) \) determined by the velocity field \( \nu(x, t) \). The initial conditions of eqs. (2.11) are given by
\[
S_n[x(0), 0] = -i\hbar \frac{\partial^n \ln[\psi(x, 0)]}{\partial x^n} \bigg|_{x(0)} .
\] (2.13)

where we have used the relation \( S(x, 0) = -i\hbar \ln[\psi(x, 0)] \) from ansatz (2.1). The wavefunction at time \( t_f \) at final position \( x(t_f) \) is given by
\[
\psi[x(t_f), t_f] = \exp \left\{ \frac{i}{\hbar} S_0[x(t_f), t_f] \right\} .
\] (2.14)
Equations (2.10)-(2.12) provide a common starting point for deriving several quantum trajectory methods such as DPM, BOMCA and ZEVCA as well as adaptive grid techniques. These methods differ from each other by the specific choice of the velocity field. For the sake of simplicity we present and compare the different methods for $N = 2$. For this case, eqs. (2.10)-(2.12) yield four equations of motion

\[
\begin{align*}
\frac{dx}{dt} &= v, \\
\frac{dS_0}{dt} &= -\frac{S_1^2}{2m} - V + vS_1 + \frac{i\hbar}{2m}S_2, \\
\frac{dS_1}{dt} &= \frac{S_1}{m}S_2 - V_1 + vS_2, \\
\frac{dS_2}{dt} &= -\frac{S_2^2}{m} - V_2.
\end{align*}
\]

The $N = 2$ case is unique for two reasons. First, it is the lowest order of truncation for which the equation of motion for the phase $S_0$ (eq. (2.11) for $n = 0$) includes a quantum potential term $\frac{i\hbar}{2m}S_2$. Second, eqs. (2.15) for BOMCA, ZEVCA and DPM yield the exact solution for an initial Gaussian wavepacket propagating in a potential with up to quadratic terms.

**III. SPECIFIC CHOICES OF TRAJECTORY VELOCITY FIELDS**

**A. Zero-Velocity Complex Action (ZEVCA)**

The simplest choice of the velocity field is

\[v(x, t) = 0 \implies x(t) = x(0).\]  

The resulting trajectories are straight lines, hence we refer to the resulting approximation as the Zero-Velocity Complex Action method [27] (ZEVCA). The ZEVCA formulation can be regarded as a hybrid between a grid method and a local semiclassical method. In reference [13], section 7.2, Wyatt considers the solution of the global hydrodynamic equations of quantum mechanics on fixed grid points (Eulerian grid) but dismisses its usefulness as a numerical tool. In reference [27], the ZEVCA formulation is shown to produce useful output from local propagation at a single grid point. In this paper we focus on the relation between BOMCA and DPM, hence we will not elaborate further here on the ZEVCA method. The interested reader is referred to [27].
B. Bohmian Mechanics with Complex Action (BOMCA)

In the BOMCA method, the velocity of the trajectories is set as

\[ v[x(t), t] = \frac{S_1[x(t), t]}{m}. \]  

(3.2)

The rationale for this choice is evident if we recall that \( S_1 \) has units of momentum and that \( S_0 \) can be associated with a quantum action field (eq.(2.3)). Inserting eq.(3.2) in eqs.(2.15) yields the \( N = 2 \) equations of motion of BOMCA

\[
\begin{align*}
\frac{dx}{dt} &= \frac{S_1}{m}, \\
\frac{dS_0}{dt} &= \frac{S_1^2}{2m} - V + \frac{i\hbar}{2m}S_2, \\
\frac{dS_1}{dt} &= -V_1, \\
\frac{dS_2}{dt} &= -V_2 - \frac{S_2^2}{m}.
\end{align*}
\]  

(3.3a-d)

The BOMCA formulation was originally presented in terms of equations of motion for partial derivatives of the velocity instead of the phase\[15\]. The transformation between the two formulations is straightforward by using relation (3.2).

Equations (3.3) have several attractive features. 1) Equations (3.3a) and (3.3c) are Newton’s second law of motion in disguise, resulting in characteristics that are classical trajectories. In other words, the \( N = 2 \) BOMCA approximation does not incorporate a quantum force in computing the trajectories. Note, however, that generally the classical trajectories take on complex values of position and momentum. This results from the complex initial momentum that emerges from eq.(2.13) for \( n = 1 \). 2) Recognizing the RHS of eq.(3.3b) as a “quantum Lagrangian”, this equation has the familiar structure of the equation of motion for the classical action, with the addition of the quantum potential. The quantum potential is the only \( \hbar \)-dependent term, hence this term is entirely responsible for incorporating the quantum effects in the \( N = 2 \) BOMCA approximation. Note that for \( N = 3 \), a quantum force term appears in the trajectory equations (specifically eq.(3.3c)), yielding complex quantum trajectories.

Equations (3.3a-d) appear in the context of other time-dependent semiclassical methods that use complex classical trajectories. The first of these is the generalized Gaussian wavepacket dynamics (GGWPD) of Huber and Heller\[28, 29\]. The two main advantages
of the BOMCA formulation over GGWP is that 1) the latter does not provide correction terms to the $N = 2$ approximation, and 2) the latter cannot be generalized to a non-Gaussian initial wavefunction. The second context in which eqs. (3.3) appear is in the first-order formulation of the complex trajectory method (CTM) of Boiron and Lombardi [30, 32]. This formulation is a complex trajectory version of time-dependent WKB. Although the CTM method is identical to BOMCA for $N = 2$, it differs at higher orders of $N$.

The propagation of complex trajectories requires the analytical continuation of the initial wavefunction to the complex plane, as well as a method to reconstruct the wavefunction on the real axis at the desired final time. Regarding the latter, in reference [15] we describe an algorithm to calculate complex initial positions that end at a final time $t_f$ on the real axis ($\Im[x(t_f)] = 0$). Without going into the details of the algorithm, suffice it to say that it exploits the local analyticity of the mapping $x(0) \rightarrow x(t_f)$. By inserting the phase $S_0$ that corresponds to these trajectories into the original ansatz (2.1), we obtain the wavefunction at a real position $x(t_f)$ at time $t_f$.

C. Derivative Propagation Method (DPM)

We present here a simplified derivation of the DPM method that yields an equivalent but more compact set of equations than has appeared previously in the literature [13]. Setting the velocity field to be

$$v[x(t), t] = \frac{\Re\{S_1[x(t), t]\}}{m} \tag{3.4}$$

and inserting eq. (3.4) into eqs. (2.15), yields the $N = 2$ DPM equations of motion:

\begin{align*}
\frac{dx}{dt} &= \frac{\Re(S_1)}{m}, \\
\frac{dS_0}{dt} &= \frac{[\Re(S_1)]^2}{2m} - V + \frac{i\hbar}{2m}S_2 + \frac{[\Im(S_1)]^2}{2m}, \\
\frac{dS_1}{dt} &= -V_1 - \frac{iS_2}{m} \Im(S_1), \\
\frac{dS_2}{dt} &= -V_2 - \frac{S_2^2}{m}. \tag{3.5}
\end{align*}

The trajectories in the DPM propagate on the real axis, removing the need to extrapolate the wavefunction to the real axis, as is required in BOMCA. But the classical structure that was evident in BOMCA is no longer present: comparing eqs. (3.3) and (3.5), we see that a quantum force term appears in the equation of motion for the momentum $S_1$ (eq. (3.5c)).
and the equation of motion for the phase $S_0$ (eq.(3.5b)) has an “extra” quantum potential term $\frac{(3S_0)^2}{2m}$.

Equations (3.5) are equivalent to those of the DPM as they appear in the literature [13, 14], as we now show. In the DPM, the wavefunction is represented by the ansatz

$$\psi(x, t) = \exp \left[ c(x, t) + i s(x, t) \right],$$

(3.6)

where $s(x, t)$ and $c(x, t)$ are real functions (ansatz (3.6) is essentially identical to the conventional Bohmian ansatz $\psi(x, t) = A(x, t) \exp \left[ \frac{i}{\hbar} s(x, t) \right]$ if one identifies $A(x, t) = \exp[c(x, t)]$).

Equating eq.(3.6) with eq.(2.1) yields

$$S(x, t) = s(x, t) - i \hbar c(x, t).$$

(3.7)

Inserting eq.(3.7) into eqs.(3.5) and dividing the results into their real and imaginary parts yields

$$\frac{d x}{d t} = \frac{s_1}{m},$$

(3.8a)

$$\frac{d s_0}{d t} = \frac{s_1^2}{2m} - V + \frac{\hbar^2}{2m}(c_2 + c_1^2),$$

(3.8b)

$$\frac{d s_1}{d t} = -V_1 + \frac{\hbar^2}{m} c_1 c_2,$$

(3.8c)

$$\frac{d s_2}{d t} = -\frac{s_2^2}{m} + \frac{\hbar^2}{m} c_2^2 - V_2,$$

(3.8d)

$$\frac{d c_0}{d t} = -\frac{s_2}{m},$$

(3.8e)

$$\frac{d c_1}{d t} = -\frac{c_1 s_2}{m},$$

(3.8f)

$$\frac{d c_2}{d t} = -\frac{2c_2 s_2}{m}.$$  

(3.8g)

These equations are equivalent to eqs.(3.5a-d), and are readily seen to be equal to eqs.(10.10) of reference [13] by taking $N = 2$ and identifying $\dot{x}(t) = \frac{s_1}{m}$.

Note that the conventional DPM equations of motion also have a quantum correction to the trajectories at truncating order $N = 2$. This can be seen in the equation for $s_1$ (eq.(3.8b)), as well as in the equations for $c_0$, $c_1$ and $c_2$ (eqs.(3.8e-g)) which have no classical counterparts. Even though the quantum force term in eq.(3.8d) is proportional to $\hbar^2$, a simple example demonstrates that this term is not small in any way compared with the classical force. Consider the harmonic oscillator potential $V(x) = \frac{1}{2}m\omega^2x^2$, where $\omega$ is the
angular frequency. The time-evolution of the ground state is

$$\psi(x, t) = \exp \left[ -\alpha_0 x^2 - \frac{i\omega}{2} t + \frac{i\gamma_0}{\hbar} \right],$$

(3.9)

where $$\alpha_0 = \frac{m\omega^2}{2\pi}$$ and $$\gamma_0 = -\frac{i\hbar}{4} \ln \left( \frac{2m\omega}{\pi} \right)$$. We recall that eqs. (3.8) (and eqs. (3.3)) yield the exact solution for an initial Gaussian wavepacket in a harmonic potential. Comparing eq. (3.6) and eq. (3.9) shows that $$s$$ is position-independent, hence, $$s_1 = 0$$. As a result, according to eq. (3.8a) the eigen-trajectories are straight lines, a result familiar from the conventional Bohmian formulation. Since $$\frac{ds_1}{dt} = 0$$, we conclude from eq. (3.8c) that the quantum force is equal in its magnitude to the classical force

$$\frac{\hbar^2}{m} c_1 c_2 = V_1[x(0)] = m\omega^2 x(0).$$

(3.10)

The LHS of this equation is the quantum force. Not only is the quantum force not negligible, we see from the RHS of eq. (3.10) that it depends linearly on the position. The appearance of a significant quantum force in this most “classical” example can be viewed as a result of working with real trajectories. In the BOMCA formulation with its complex trajectories, the quantum force vanishes in this case, which is one of the strongest motivations for studying BOMCA [15].

IV. INTERFERENCE WITH REAL TRAJECTORIES

As mentioned in the Introduction, the nodal problem is currently the main obstacle to performing numerical calculations using Bohmian mechanics. In this section, we present preliminary results showing that an oscillatory wavefunction in close agreement with the quantum result can be obtained using eqs. (2.15) with real trajectories. Consider an initial Gaussian wavepacket

$$\psi(x, 0) = \exp \left[ -\alpha_0 (x - x_c)^2 + \frac{i}{\hbar} p_c (x - x_c) + \frac{i}{\hbar} \gamma_0 \right],$$

(4.1)

propagating in a Morse potential

$$V(x) = A \left\{ [1 - \exp(-\beta x)]^2 - 1 \right\}.$$

(4.2)

The parameters of the initial Gaussian are $$\alpha_0 = 0.5$$, $$x_c = 9.342$$, $$p_c = 0$$, $$\gamma_0 = -\frac{i\hbar}{4} \ln \left( \frac{2m\omega}{\pi} \right)$$ where we take $$m = \hbar = 1$$ (all quantities are given in atomic units). As for the Morse
FIG. 1: An initial Gaussian wavepacket propagating in a Morse potential. The parameters of the system are given in the text. The final propagation time $t_f$ equals roughly half of the oscillation period of a classical particle located at the center of the initial Gaussian, $x_c$. The exact wavefunction was calculated using the split operator method with a Fourier basis.

parameters, $A = 10.25$ and $\beta = 0.2209$. The final propagation time, $t_f = 5.93$, is chosen so as to produce a strongly oscillating pattern. Figure 1 depicts the potential and wavefunctions.

In both DPM and BOMCA the velocity is taken to be a function of $S_1$: in DPM, $v = \Re \left( \frac{S_1}{m} \right)$ while in BOMCA, $v = \frac{S_1}{m}$. We now present an alternative procedure; we take $v$ to be completely independent of $S_1$ and set a classical equation of motion for $v$:

$$\frac{dv}{dt} = -\frac{V_1[x(t)]}{m}.$$  \hspace{1cm} (4.3)

Equation (4.3) is then supplemented to the set of eqs. (2.15). Furthermore, we extend the freedom in the choice of the velocity field to include the initial conditions for the velocity, which we take to be

$$v[x(0), 0] = \frac{3\{S_1[x(0), 0]\}}{m} = \frac{2\alpha_0}{m} [x(0) - x_c];$$  \hspace{1cm} (4.4)

$S_1[x(0), 0]$ is obtained by inserting eq. (4.1) into eq. (2.13) and setting $n = 1$. Equation (4.4) defines real initial conditions; taken together with eqs. (4.3) and (2.15a) this yields real classical trajectories (note that if we had taken the initial velocity to be complex, $v[x(0), 0] = \frac{S_1[x(0), 0]}{m}$, we would have obtained the BOMCA equations, eqs. (3.3)). The next
FIG. 2: Real classical trajectories obtained by solving Newton’s second law of motion (eq.(4.3)) for a Morse potential (eq.(4.2)) with initial conditions (4.4). The parameters of the propagation are given in the text. The final propagation time $t_f$ is marked explicitly. The trajectories can be divided into two overlapping branches. The first branch (marked as solid lines) is the locus of trajectories that have reached their classical turning point and were reflected by the exponential barrier of the potential. The second branch (marked as dashed lines) is the locus of trajectories that by $t_f$ did not reach their classical turning point.

step is to solve eqs.(2.15) and (4.3) with initial conditions (2.13) and (4.4), respectively, for a series of initial positions $\{x(0)\}$ in the vicinity of $x_c$. The wavefunction at time $t_f$ at final position $x_f$ is given by eq.(2.14), where $S_0[x(t_f), t_f]$ is the solution of eq.(2.15b).

In fig.2 we plot the trajectories obtained. The trajectories can be divided into two overlapping groups that we refer to as branches. The first (reflected) branch (marked as solid lines) is the locus of trajectories that have reached their classical turning point and were reflected by the exponential barrier of the potential. The second branch (marked as dashed lines) is the locus of trajectories that by $t_f$ did not reach their classical turning point. Thus, to an arbitrary final position $x$ ($x \gtrsim -2.8$) these correspond two initial positions and two associated trajectories.

The question arises, if two trajectories and therefore two values of $S_0(x, t_f)$ correspond to each final position $x$, how should we determine the wavefunction $\psi(x, t_f)$? The clear distinction between the two branches allows us to associate a wavefunction with each branch,
which we will call $\psi_1(x, t_f)$ and $\psi_2(x, t_f)$. We apply the superposition principle to reconstruct the wavefunction at $x$, obtaining

$$\psi(x, t_f) = \psi_1(x, t_f) + \psi_2(x, t_f).$$

(4.5)

In fig.3 we compare the exact wavefunction along with $|\psi_1(x, t_f)|$, $|\psi_2(x, t_f)|$ and $|\psi(x, t_f)| = |\psi_1(x, t_f) + \psi_2(x, t_f)|$. For values of $x$ larger than $\approx -2.8$ (the position of the maximum of $|\psi(x, t_f)|$), the superposition yields a surprisingly accurate approximation of the oscillating wavefunction: even though the wavefunctions $\psi_1(x, t_f)$ and $\psi_2(x, t_f)$ exhibit no oscillations whatsoever, their superposition yields strong oscillations and a node near the maximum.

Note that $\psi_2(x, t_f)$ provides the “main” contribution to the final wavefunction; $\psi_1(x, t_f)$, which originates from the reflected branch, contributes to $\psi(x, t_f)$ only where the wavefunction oscillates. As the classical turning point is approached, the amplitudes arising from the different branches diverge and the superposition of contributions appears to have no physical significance.

As noted above, the BOMCA equations for $N = 1$ are identical to those of Generalized Gaussian Wavepacket Dynamics (GGWPD). In both cases, the trajectories that are propagated obey classical equations of motion but are complex. In this section we described a modification of BOMCA in which the classical trajectories are taken to be real. It is interesting to speculate if there might be a connection with thawed Gaussian propagation, in which the equations of motion are the same as those for GGWPD, but the trajectories are real. Consistent with this conjecture is the observation that in thawed Gaussian propagation there is no need for a root search, as is true in the real-trajectory version of BOMCA. However, the correspondence cannot be exact. In the real-trajectory version of BOMCA, in principle every point in coordinate space is propagated, whereas in thawed Gaussian propagation the initial wavefunction is decomposed into Gaussians and any decomposition that satisfies completeness is allowed. Moreover, in real-trajectory BOMCA the trajectories have no width and no functional form whereas in thawed Gaussian propagation there is always some residual signature of the Gaussian decomposition. For example, Gaussians that reach the turning point have part of their amplitude extending into the classically forbidden region, whereas in real-trajectory BOMCA such penetration into the classically forbidden region is absent.
FIG. 3: A comparison between the exact wavefunction with the contribution of the first branch $|\psi_1(x, t_f)|$, the second branch $|\psi_2(x, t_f)|$ and a superposition of both $|\psi(x, t_f)| = |\psi_1(x, t_f) + \psi_2(x, t_f)|$. For $x \gtrsim -2.8$ (the position of the maximum of the exact wavefunction) the superposition procedure yields a surprisingly accurate approximation of the oscillating wavefunction: even though the wavefunctions $|\psi_1(x, t_f)|$ and $|\psi_2(x, t_f)|$ exhibit no oscillations whatsoever. The procedure is undefined in the classically forbidden region which the classical trajectories cannot access. The exact wavefunction was calculated using the split operator method with a Fourier basis.

V. SUMMARY

We have presented a unified and compact derivation of Bohmian methods that serves as a common starting point for several approximations. In particular, the new approach was used to derive and compare the DPM, BOMCA and ZEVCA methods. We focused on the role of the quantum force in the DPM and BOMCA methods, and showed that for $N = 2$, the lowest order of truncation for which a quantum potential is present, the BOMCA formulation is closer to the classical equations of motion than DPM, although the trajectories are complex. We also demonstrated that an interference pattern can be obtained by superposing the contributions from real classical trajectories in what is otherwise essentially a Bohmian formulation.

Since nodes in quantum mechanics arise from interfering amplitudes, it is only natural to attempt to solve the nodal problem in Bohmian mechanics by applying the superposition...
principle. This suggests decomposing the wavefunction into two nodeless parts and propagating each part separately using trajectories [11, 31]. However, since nodeless wavefunctions do not generally remain nodeless, this approach generally requires a series of time-dependent decompositions of the total wavefunction. Such decompositions are numerically inconvenient, largely arbitrary, and typically valid only for relatively short times. In the scheme we presented, an oscillatory wavefunction is successfully decomposed for all times considered into two nodeless, non-oscillatory parts, $\psi_1$ and $\psi_2$. As such, the scheme represents a promising new avenue for dealing with the challenging problem of nodes in Bohmian mechanics. We are currently exploring an analogous idea of applying the superposition principle to complex crossing trajectories in BOMCA [16] and in time-dependent WKB [32]; the results are very promising and will be published elsewhere. In addition, although we do not yet have final results, it seems that path integral techniques can provide a rigorous justification of the superposition principle in Bohmian methods and the limits of its applications.
