Abstract

NADPH oxidase is a crucial enzyme in mediating antimicrobial host defense and in regulating inflammation. Patients with chronic granulomatous disease, an inherited disorder of NADPH oxidase in which phagocytes are defective in generation of reactive oxygen intermediates (ROIs), suffer from life-threatening bacterial and fungal infections. The mechanisms by which NADPH oxidase mediate host defense are unclear. In addition to ROI generation, neutrophil NADPH oxidase activation is linked to the release of sequestered proteases that are posited to be critical effectors of host defense. To definitively determine the contribution of NADPH oxidase versus neutrophil serine proteases, we evaluated susceptibility to fungal and bacterial infection in mice with engineered disruptions of these pathways. NADPH oxidase-deficient mice (p47phox−/−) were highly susceptible to pulmonary infection with Aspergillus fumigatus. In contrast, double knockout neutrophil elastase (NE)−/−×cathespain G (CG)−/− mice and lysosomal cysteine protease cathepsin D/dipeptidyl peptidase I (DPPI)-deficient mice that are defective in neutrophil serine protease activation demonstrated no impairment in antifungal host defense. In separate studies of systemic Burkholderia cepacia infection, uniform fataly occurred in p47phox−/− mice, whereas NE−/−×CG−/− mice cleared infection. Together, these results show a critical role for NADPH oxidase in antimicrobial host defense against A. fumigatus and B. cepacia, whereas the proteases we evaluated were dispensable. Our results indicate that NADPH oxidase dependent pathways separate from neutrophil serine protease activation are required for host defense against specific pathogens.

Introduction

Chronic granulomatous disease is an inherited disorder of the NADPH oxidase in which phagocytes are defective in generation of superoxide anion and downstream reactive oxidant intermediates (ROIs). As a result of this defect, CGD patients suffer from recurrent life-threatening bacterial and fungal infections [1]. Among CGD patients, the degree of impairment of NADPH oxidase in neutrophils correlates with clinical disease severity [2]. Although the critical role of the phagocyte NADPH oxidase has been established for decades [3], the precise mechanisms by which NADPH oxidase mediates antimicrobial host defense are not well understood.

One mechanism by which NADPH oxidase can kill or injure pathogens is through the direct toxic effects of ROIs. The rapid activation of NADPH oxidase constitutes an emergency response to invading pathogens, and occurs in response to several stimuli such as formylated peptides, opsonized particles, integrin-dependent adhesion [4,5], and ligation of specific pathogen recognition receptors (e.g., dectin-1 [6]). Syk and class IIA phosphoinositide 3-kinases regulate neutrophil NADPH oxidase activation by Aspergillus fumigatus hyphae [7]. Upon activation of the oxidase, the cytoplasmic subunits p47phox, p67phox, and p40phox and Rac translocate to the membrane-bound heterodimer cytochrome comprised of gp91phox and p22phox. Molecular oxygen is converted to superoxide anion, which can spontaneously or enzymatically be converted to cytotoxic metabolites, including H2O2, hydroxyl anion, and peroxynitrite anion. In neutrophils, myeloperoxidase catalyzes the conversion of H2O2 to hypohalous acid, which is potentially microbicidal.

In addition to the direct injurious effect of ROIs against pathogens, NADPH oxidase may mediate host defense by activation of pre-formed neutrophil serine proteases. In resting neutrophils, the flavocytochrome subunits gp91phox and p22phox are...
NADPH Oxidase and Neutrophil Proteases

Results

Neutrophil elastase−/− × cathepsin G−/− mice have intact host defense in pulmonary aspergillosis, whereas NADPH oxidase-deficient p47phox−/− mice succumb to infection.

Invasive aspergillosis is a major cause of morbidity and mortality in CGD patients [19,20,21,22,23], and NADPH oxidase-deficient mice are similarly highly susceptible to experimental aspergillosis [24,25,26,27,28]. Prior studies showed that NE−/− × CG−/− mice also had increased susceptibility compared to WT mice in a model of systemic aspergillosis [15]. We therefore asked whether NADPH oxidase-mediated antifungal host defense principally occurs via neutrophil serine protease-independent pathways.

To address this question, we evaluated experimental aspergillosis in 3 groups of mice: 1) WT (C57BL/6) mice; 2) p47phox−/− (CGD) mice; and 3) NE−/− × CG−/− mice. Prior studies from our and other laboratories showed that WT C57BL/6 mice can clear an intratracheal inoculum of A. fumigatus >10^7 conidia (spores) per mouse [25,29]. In contrast, we previously found that the LD50 in unmanipulated p47phox−/− mice is <10^7 conidia/mouse [25]. We therefore selected a high inoculum (1.25×10^7 conidia/mouse) and a low inoculum (1.25×10^5 conidia/mouse) to evaluate susceptibility to aspergillosis.

Following oropharyngeal challenge with 1.25×10^4 conidia/mouse, all CGD mice died by 12 days, whereas WT and NE−/− × CG−/− mice had uniform survival (Figure 1A). When administered the high inoculum (1.25×10^7 conidia/mouse), all CGD mice died within 3 days, whereas all WT and NE−/− × CG−/− mice survived (Figure 1B). Thus, the LD50 of the A. fumigatus inoculum is more than 1000-fold greater in NE−/− × CG−/− mice versus CGD mice.

Since we established that NE and CG deficiency does not recapitulate the CGD phenotype in experimental pulmonary aspergillosis, our subsequent experiments focused on evaluating
host defense responses in NE<sup>−/−</sup> × CG<sup>−/−</sup> mice compared to WT mice. WT and NE<sup>−/−</sup> × CG<sup>−/−</sup> mice administered a high A. fumigatus inoculum (1.25 × 10<sup>7</sup> conidia/mouse) were sacrificed on day 3. BALF leukocytosis and extent of lung inflammation were similar between the two genotypes (Figure 2A and B). Lung histology showed a consistent pattern in both genotypes, characterized predominantly by peribronchovascular inflammation (Figure 2 C–F). The inflammatory cell type was mixed, consisting of neutrophils, macrophages and lymphocytes. With GMS staining, we could not identify invasive parenchymal hyphae in any of the lung sections. However, there appeared to be hyphal fragments and debris within inflammatory lesions. Taken together, these findings suggest that the NE<sup>−/−</sup> × CG<sup>−/−</sup> mice have an impaired innate immune response to A. fumigatus compared to WT mice.

![Figure 2. Lung histology and airway inflammation in WT and NE<sup>−/−</sup> × CG<sup>−/−</sup> mice after A. fumigatus administration.](image-url) Mice were administered A. fumigatus (1.25 × 10<sup>7</sup> conidia per mouse) by oropharyngeal aspiration and sacrificed on day 3. A) BALF leukocyte recovery and B) percent lung inflammation were similar in WT and NE<sup>−/−</sup> × CG<sup>−/−</sup> mice. Representative lung histology from WT (C and D) and NE<sup>−/−</sup> × CG<sup>−/−</sup> mice (E and F). Predominantly peribronchovascular neutrophilic and lymphohistiocytic inflammation occurred in both genotypes (C and E; H&E, 40×). GMS staining (400×) of lung sections from WT (D) and NE<sup>−/−</sup> × CG<sup>−/−</sup> (F) mice showed what appeared to be degenerated hyphal fragments, but no evidence of intact invasive hyphae. Results are representative of 15 WT and 10 NE<sup>−/−</sup> × CG<sup>−/−</sup> mice. By comparison, p47<sup>phox</sup><sup>−/−</sup> mice administered A. fumigatus at 0.1% of this inoculum (1.25 × 10<sup>5</sup> conidia per mouse) and sacrificed on day 3 had evidence of fungal pneumonia characterized by G) multiple foci of neutrophilic consolidation (H&E, 40×), and H) hyphal parenchymal invasion (arrow) (GMS, 400×).

doi:10.1371/journal.pone.0028149.g002
we could not identify a clear difference in airway or parenchymal inflammation between the genotypes, and, by histological criteria, both genotypes were able to prevent invasive fungal disease. In contrast, p47<sup>phox</sup>−/−×CG<sup>−/−</sup> mice administered a low inoculum (1.25×10<sup>3</sup> conidia/mouse) developed neutrophilic consolidative lesions associated with invasive fungal disease (Figure 2G and H).

We next performed a more detailed assessment of fungal burden, comparing WT and NE<sup>−/−</sup>×CG<sup>−/−</sup> mice on day 3 following A. fumigatus (1.25×10<sup>3</sup> conidia/mouse) challenge. There was no significant difference in quantitative fungal cultures of lungs nor was there a difference in serum or BALF galactomannan levels between the genotypes (Figure 3A–C). Thus, our data point to a dispensable role of NE and CG in host defense against pulmonary aspergillosis.

We considered the possibility that other neutrophil serine proteases may compensate for the lack of NE and CG levels. DPPI<sup>−/−</sup> mice have severe deficiency of these proteases [30]. We administered A. fumigatus (1.25×10<sup>3</sup> conidia/mouse) to WT and DPPI<sup>−/−</sup> mice and assessed lung histology on day 3. Lung inflammation was mild in both genotypes, predominantly confined to peribronchovascular areas (Figure 4A and B). Similar to NE<sup>−/−</sup>×CG<sup>−/−</sup> mice, we did not find evidence of hyphal parenchymal invasion in DPPI<sup>−/−</sup> mice (Figure 4C and D). Thus, using two different neutrophil protease-deficient models, we did not identify a role for these proteases in host defense against pulmonary aspergillosis.

NADPH is required, but neutrophil elastase and cathepsin G are dispensable, in defense against systemic

*Burkholderia cepacia*

We next considered whether NE and CG are required for host defense against systemic *B. cepacia* challenge. *B. cepacia* was selected specifically because it is an important bacterial pathogen in patients with CGD [22,23] (and patients with cystic fibrosis), but generally not in other immunocompromised patients such as those with prolonged neutropenia or receiving immunosuppressive therapy. Studies of human neutrophils show that killing of *B. cepacia* is NADPH oxidase-dependent [31], and CGD mice have increased susceptibility to *B. cepacia* challenge [28,32,33,34]. Thus, *B. cepacia* infection is an excellent model to evaluate NADPH oxidase-dependent antibacterial host defense.

WT, p47<sup>phox</sup>−/− and NE<sup>−/−</sup>×CG<sup>−/−</sup> mice were administered intraperitoneal 4×10<sup>7</sup> colony forming units (CFUs) of *B. cepacia*, and time to mortality was followed. Mortality occurred within 4 to 6 days following challenge in p47<sup>phox</sup>−/− mice, whereas all WT and NE<sup>−/−</sup>×CG<sup>−/−</sup> mice survived (Figure 5A). In separate experiments, mice were administered *B. cepacia* (4×10<sup>7</sup> CFU), sacrificed at 24 h, and quantitative cultures were performed on blood, peritoneum, kidneys and spleens. Blood cultures from the three genotypes showed no growth. Bacterial recovery from peritoneal cavities and spleens was significantly greater in p47<sup>phox</sup>−/− mice compared to WT and NE<sup>−/−</sup>×CG<sup>−/−</sup> mice (Figure 5B). Thus, similar to *A. fumigatus*, NADPH oxidase was critical in host defense against *B. cepacia*, while NE and CG were dispensable.

**Discussion**

Our results show that NADPH oxidase is essential in defending against *A. fumigatus* and *B. cepacia*, but does so independently of neutrophil serine proteases. In two models of engineered protease-deficient mice, host defense was intact against *A. fumigatus* and *B. cepacia*, two major pathogens in CGD patients. These results do not exclude the possibility that neutrophil serine proteases may have a more central role in host defense against other pathogens that cannot be compensated by NADPH oxidase-dependent pathways.
Our results support a model in which NADPH oxidase and neutrophil serine proteases have distinct antibacterial and antifungal effector functions rather than protease activation being the central mechanism by which NADPH oxidase mediates host defense.

Consistent with this notion, patients with CGD and Papillon-Lefèvre syndrome (who lack functional DPPI) suffer from recurrent infections, but the spectrum of pathogens differs between the two diseases. An important consideration is that defects in neutrophil-mediated killing in ex vivo studies may not be recapitulated in vivo regarding susceptibility to infection. In addition, neutrophil serine protease deficiency may be compensated for by other neutrophil effector pathways. Bianchi et al. [35] identified calprotectin as a NET constituent mediating anti-Aspergillus host defense. Indeed, neutrophils are armed with several antimicrobial agents, including lactoferrin [36], lysozyme, and defensins. Potentially, NADPH oxidase-induced serine protease activation may be important for defense against certain pathogens but play a redundant role in defense against others.

There may also be pathogen-related differences that influence susceptibility to neutrophil proteases. Belaaouaj et al. [11] showed an important function of neutrophil elastase in defending against certain Gram-negative ( Klebsiella pneumoniae and Escherichia coli) but not Gram-positive ( Staphylococcus aureus) bacteria in mice. However, neutrophils from patients with Papillon-Lefèvre syndrome (who lack functional DPPI) do not have a uniform defect in killing Staphylococcus aureus and Escherichia coli, suggesting that neutrophil serine proteases may not be the major pathway used by human neutrophils to kill specific bacteria [16]. In addition, our experiments focused on acute infection models with early time points for analysis. Potentially, we may have identified differences in host defense between wildtype and protease-deficient mice had we included higher inocula of pathogens and/or different time points for analysis.

Tkalec et al. [15] previously showed that NE−/− x CG−/− mice were more susceptible to intravenous Aspergillus administration compared to WT mice based on survival and fungal burden in kidneys. This apparent discrepancy with our findings is likely in part related to the route of Aspergillus administration. We used oropharyngeal aspiration because inhalation is by far the most common portal of entry of Aspergillus species. There are likely critical features of pulmonary host defense that are not reflected in the intravenous model. For example, inhaled conidia are phagocytosed by alveolar macrophages, where NADPH oxidase can play a role in restricting germination of Aspergillus conidia [37]. Neutrophil elastase and cathepsin G can promote coagulation and intravascular thrombus growth in vivo that restricts tissue bacterial invasion [38]; conceivably, this pro-thrombogenic effect of neutrophil proteases may limit tissue invasion of intravenously administered fungus, but be less relevant following intrapulmonary challenge. Another difference is the strains of mice used for the studies: we used NE−/− x CG−/− mice backcrossed to C57BL/6 whereas the mice used by Tkalec et al. [15] were backcrossed to the 129Sv strain. There can be important mouse strain-specific differences in susceptibility to aspergillosis [39] that can influence the relative importance of specific host defense pathways.

Neutrophil serine proteases have also been shown to contribute to pathogen killing through formation of neutrophil extracellular traps (NETs). Upon activation, neutrophils release granule proteins and chromatin that co-mingle in the extracellular environment to form NETs. These NETs bind to and kill bacteria and degrade bacterial virulence factors [40], and target fungi [41,42]. Release of NETs requires death of neutrophils and breakdown of cell membranes, and has been linked to NADPH oxidase activation and autophagy [43,44]. NADPH oxidase-mediated NET formation involves complex intracellular signaling, including activation of the Raf-MEK-ERK and upregulation of antiapoptotic proteins [45], and production of interferon-gamma...
NADPH oxidase is a critical regulator of antibacterial and antifungal host defense and of inflammation. Studies of protease-deficient mice and patients with Papillon-Léfevre syndrome point to neutrophil proteases also having an important host defense function. These results and those of our study support a model in which NADPH oxidase-regulated antimicrobial pathways have distinct pathogen-specific functions in which certain pathogens are sensitive to the direct antimicrobial effect of ROIs whereas others may be controlled by neutrophil serine proteases and other NET constituents.

Methods

Ethics statement

All procedures performed on animals in this study were approved by the Animal Care and Use Committee at Roswell Park Cancer Institute, and complied with all state, federal, and NIH regulations.

Mice

Mice with a targeted disruption of the p47^{phox} gene have a defective NADPH oxidase, rendering phagocytes incapable of generating measurable superoxide [60]. NADPH oxidase-deficient mice have increased susceptibility to pathogens that afflict CGD patients, including Aspergillus species [24,25,27] and B. cepacia [28,32,33,34]. p47^{phox/-} mice were derived from C57BL/6 and 129 intercrosses, and backcrossed 14 generations (N14) in the C57BL/6 background. NE^{-/-} mice [11] and CG^{-/-} mice [14] were intercrossed to generate double knockout NE^{-/-} x CG^{-/-} mice (N10 in C57BL/6) [51]. Dipeptidyl peptidase I (DPPI) is a lysosomal cysteine protease required for the activation of granule-associated serine proteases, including NE, CG, and proteinase 3. DPPI^{-/-} mice (N11 in C57BL/6) were generated as previously described [50]. Microsatellite typing performed at the Washington University Rheumatic Disease Core Center’s Speed Congenics Laboratory showed the NE^{-/-} x CG^{-/-} mice and DPPI^{-/-} mice to be 97.7% and 99.2% C57BL/6, respectively. Age (8–15 weeks) and sex matched C57BL/6 WT mice were used as controls. Mice were bred and maintained under specific pathogen free conditions at the animal care facility at Roswell Park Cancer Institute, Buffalo, NY.

Administration of A. fumigatus

A clinical isolate of A. fumigatus was used in all experiments [25]. Conidial suspensions were prepared as previously described [25], diluted to desired concentrations, and administered by oropharyngeal aspiration. We found that oropharyngeal aspiration leads to similar degrees of fungal pneumonia and mortality in p47^{phox/-} mice compared to intratracheal administration, but avoids surgery. Mice were anesthetized by isofluorane inhalation using an approved chamber. Following anesthesia, mice were suspended by their upper incisors from a suture thread on a 90° incline board. The tongue was gently extended, and a liquid volume (maximum 50 μl) was delivered into the distal part of the oropharynx. With the tongue extended, the animal was unable to swallow, and the liquid volume was aspirated into the lower respiratory tract. Just prior to liquid delivery, the chest was gently compressed and then released just after deposition of liquid into the oropharynx to enhance aspiration of the liquid into the lung. Mice recovered within 5 minutes of the procedure, and were observed until they resumed normal activity.

Bronchoalveolar fluid collection and cytology

After sacrifice, BALF collection was performed as previously described [55]. The trachea was cannulated with a 22-gauge i.v. catheter. Using a tuberculin syringe, 1000 μl PBS was injected...
and withdrawn from the lung and again fresh 1000 μL PBS was injected and withdrawn from the lung and both were pooled. Cells were pelleted by centrifugation at 1,500 g for 3 min. Supernatants were aliquoted and stored at −80°C. In the cell pellet, the red blood cells (RBCs) were removed by ACK lysis, and the cells were suspended in 1 ml of PBS. The total number of leukocytes/ml was counted using a hemocytometer. Cells were then cytocentrifuged onto clean glass slides and stained with the Hema 3 stain set (Fisher Scientific, Pittsburgh, PA, USA), and cell differential counts were assessed blinded to genotype.

Histopathology

After sacrifice and bronchoalveolar lavage, mouse lungs were inflated with 10% neutral buffered formalin via the trachea. Paraffin-embedded blocks were prepared and sections were stained with Hematoxylin and Eosin (H&E) to assess inflammation and Grocott-Gomori methenamine-silver stain (GMS) to visualize fungi. Tissues were microscopically examined for pulmonary injury, vascular invasion, and structural changes in *Aspergillus* hyphae. All slides were analyzed by one of us [BHS] using 40× magnification without formal morphometric analysis, and blinded to genotype. The percentage of lung involved by inflammation was scored in each mouse as follows: 0%, 5%, 10%, and then by 10% increments (e.g., 20%, 30%, 40%, etc.). The predominant inflammatory cell type was scored.

Assessment of fungal burden

Fungal burden was assessed in four ways. (i) The presence of invasive hyphae in lungs was determined by histology. (ii) Quantitative cultures of lung homogenates were performed using a previously validated method [61]. Lungs were weighed, placed in a sterile polyethylene bag (Tekmar Corp., Cincinnati, Ohio), and homogenized with sterile saline for 30 s (Stomacher 80; Tekmar Corp., Cincinnati, Ohio). Lung homogenate dilutions (10⁻¹ and 10⁻²) were prepared in sterile saline. Aliquots (100 μL) from homogenates and homogenate dilutions were plated on Sabouraud glucose agar plates. After inoculation, plates were incubated for 24 h, and then left at room temperature for another 24 h. The number of colony forming units (CFUs) of *A. fumigatus* was counted, and the CFUs per gram was calculated. A finding of one colony of *A. fumigatus* was considered positive. (iii) Galactomannan is a fungal cell wall product. The serum concentration of galactomannan is directly related to the concentration of *A. fumigatus* in lung tissue of experimental invasive pulmonary aspergillosis [62,63]. Detection of galactomannan is used clinically as a diagnostic adjunct for invasive aspergillosis [64]. Batched frozen serum samples from infected and sham-infected mice were thawed, and galactomannan levels were quantitated using Platelia Aspergillus enzyme immunoassay (Bio-Rad Laboratories, Redmond, WA) per the manufacturer’s instructions. (iv) BALF galactomannan levels were determined using the same assay.

Galactomannan concentrations in BALF also correlate directly with concentrations of *A. fumigatus* in lung tissue [65].

**Administration of Burkholderia cepacia**

We used a *B. cepacia* strain isolated from a CGD patient [33]. Bacteria were stored in Lennox broth [Invitrogen] at −80°C until use. Aliquots of frozen bacteria were thawed, inoculated into Lennox broth, and grown with shaking at 37°C overnight. The bacteria were washed twice in DPBS, and bacterial density was determined by absorption at 630 nm at dilutions corresponding to the linear portion of the absorbance-bacterial density curve. To confirm the bacterial density, aliquots were serially diluted and sub-cultured in duplicate on Lennox agar plates, and colony forming units were counted. Mice were injected intraperitoneally with 0.2 ml of bacteria at the desired concentration. One set of mice was followed for survival, while bacterial clearance was assessed 24 hours after challenge in a second set of mice. In this second set of mice, blood was collected retro-orbitally into Z (no additive tube) microtainers (BD Biosciences). Peritoneal lavage was performed with 10 ml of DPBS, and spleens and kidneys were harvested and homogenized in 2 ml of DPBS. Samples were diluted in serial 10-fold dilutions and inoculated in duplicate onto Lennox agar plates. After inoculation, plates were incubated for 24 to 48 h at 37°C and colonies were enumerated.

**Time to euthanasia**

Following infection, mice were monitored twice daily for death and morbidity until at least day 25. Mice with pre-specified criteria for distress that included inability to feed or drink, labored breathing, or general moribund appearance were euthanized by CO₂ asphyxiation.

**Statistical Analysis**

Kaplan-Meier curves were generated for each population for time to euthanasia experiments (Graph Pad Prism 4.0) and analyzed using the log-rank method. In experiments involving quantitation of bacterial and fungal burden, inter-group comparisons were made using the non-parametric Mann-Whitney method. In cases in which bacterial cultures were sterile in all mice in a given group, Wilcoxon Signed Rank test was used for inter-group comparisons. A two-sided p value of <0.05 was considered to be statistically significant.
