NEUTRINO OSCILLATIONS:
CURRENT STATUS AND PROSPECTS*

THOMAS SCHWETZ

(Received October 26, 2005)

I summarize the status of neutrino oscillations from world neutrino oscillation data with date of October 2005. The results of a global analysis within the three-flavor framework are presented. Furthermore, a prospect on where we could stand in neutrino oscillations in ten years from now is given, based on a simulation of upcoming long-baseline accelerator and reactor experiments.

PACS numbers: 14.60.Pq

1. Introduction

In the last ten years or so we have witnessed huge progress in neutrino oscillation physics. The outstanding experimental results lead to quite a clear overall picture of the neutrino sector. We know that there are two mass-squared differences separated roughly by a factor of 30, and in the lepton mixing matrix there are two large mixing angles, and one mixing angle which has to be small. In the first part of this talk I review the present status of neutrino oscillations by reporting the results of a global analysis of latest world neutrino oscillation data from solar, atmospheric, reactor and accelerator experiments. This analysis is performed in the three-flavor framework and represents an update of the work published in Refs. [1, 2].

The recent developments in neutrino oscillations triggered a lot of activity in the community, and many new neutrino oscillation experiments are under construction, or under active investigation, to address important open questions, such as the value of the small mixing angle $\theta_{13}$, leptonic CP violation and the type of the neutrino mass hierarchy. In the second part of the talk I try to give an outlook, where we could stand in about ten years from

* Presented at the XXIX International Conference of Theoretical Physics, “Matter to the Deepest”, Ustroń, Poland, September 8–14, 2005.

(3203)
now. These results are based on a simulation of up-coming long-baseline accelerator and reactor experiments, which are expected to deliver physics results within the anticipated time scale \[3, 4\].

Three-flavor neutrino oscillations are described in general by the two independent mass-squared differences \(\Delta m_{21}^2, \Delta m_{31}^2\), three mixing angles \(\theta_{12}, \theta_{23}, \theta_{13}\), and one complex phase \(\delta_{\text{CP}}\). Throughout this work I will use the standard parameterization for the PMNS lepton mixing matrix

\[
U = \begin{pmatrix}
1 & 0 & 0 \\
0 & c_{23} & s_{23} \\
0 & -s_{23} & c_{23}
\end{pmatrix}
\begin{pmatrix}
c_3 & 0 & e^{-i\delta_{\text{CP}} s_{13}} \\
0 & 1 & 0 \\
-e^{i\delta_{\text{CP}} s_{13}} & 0 & c_{13}
\end{pmatrix}
\begin{pmatrix}
c_{12} & s_{12} & 0 \\
-s_{12} & c_{12} & 0 \\
0 & 0 & 1
\end{pmatrix},
\]

with the abbreviations \(s_{jk} \equiv \sin \theta_{jk}, c_{jk} \equiv \cos \theta_{jk}\). The type of the neutrino mass hierarchy is determined by the sign of \(\Delta m_{31}^2\): \(\Delta m_{31}^2 > 0\) corresponds to the normal hierarchy and \(\Delta m_{31}^2 < 0\) to the inverted one.

### 2. Present status of three-flavor neutrino oscillations

I summarize the present status of three-flavor neutrino oscillation parameters in Table I. The numbers are obtained from a global analysis of current oscillation data from solar \[5–7\], atmospheric \[8\], reactor \[9, 10\], and accelerator \[11\] data. Details of the analysis can be found in Ref. \[2\] and references therein. In the following I give some brief comments on the determination of the “atmospheric” and the “solar” parameters, and on the bound on \(\theta_{13}\).

| parameter                           | bf±1\(\sigma\) | 1\(\sigma\) acc. | 3\(\sigma\) range |
|------------------------------------|----------------|------------------|------------------|
| \(\Delta m_{21}^2\, [10^{-5}\text{eV}^2]\) | 7.9 ± 0.3      | 4\%              | 7.1 – 8.9        |
| \(|\Delta m_{31}^2|\, [10^{-3}\text{eV}^2]\) | 2.2_{0.27}^{+0.37} | 14\%             | 1.4 – 3.3        |
| \(\sin^2\theta_{12}\)            | 0.31_{-0.03}^{+0.02} | 9\%              | 0.24 – 0.40      |
| \(\sin^2\theta_{23}\)            | 0.50_{-0.05}^{+0.06} | 11\%             | 0.34 – 0.68      |
| \(\sin^2\theta_{13}\)            | –              | –                | \(\leq 0.046\)   |

The “atmospheric parameters”. In Fig. 1 I show the allowed regions for \(\theta_{23}\) and \(\Delta m_{31}^2\) from separate analyses of Super-K atmospheric neutrino data \[8\], and data from the K2K long-baseline experiment \[11\]. The latter probes the \(\nu_\mu\) disappearance oscillation channel in the same region of \(\Delta m^2\).
as explored by atmospheric neutrinos. The neutrino beam is produced at
the KEK proton synchrotron, and originally consists of 98% muon neutrinos
with a mean energy of 1.3 GeV. The $\nu_\mu$ content of the beam is observed at
the Super-K detector at a distance of 250 km, where 107 events have been
detected, whereas $151^{+12}_{-10}$ have been expected for no oscillations. Fig. 1
illustrates that the neutrino mass-squared difference indicated by the $\nu_\mu$
disappearance observed in K2K is in perfect agreement with atmospheric
neutrino oscillations. Hence, K2K data provide the first confirmation of os-
cillations with $\Delta m^2_{31}$ from a man-made neutrino source. K2K gives a rather
weak constraint on the mixing angle due to low statistics in the current data
sample, and the constraints on $\sin^2 \theta_{23}$ of Table I are dominated by atmo-
spheric data. Both data sets give a best fit point of $\theta_{23} = \pi/4$, i.e. maximal
mixing.

![Fig. 1. Allowed regions for $\sin^2 \theta_{23}$ and $\Delta m^2_{31}$ at 90%, 95%, 99%, and 3$\sigma$ C.L. for atmospheric neutrino data (contour lines) and the K2K long-baseline experiment (colored regions).](image)

In our analysis of atmospheric neutrino data we neglect the small con-
tribution of oscillations with $\Delta m^2_{21}$. Taking into account this sub-leading
effect, in Refs. [12, 13] a small deviation from maximal mixing was found,
due to an excess of sub-GeV $e$-like events. This indication currently is not
statistically significant (about 0.5 $\sigma$), and so-far it has not been confirmed
by a three-flavor analysis of the Super-K collaboration [14].

The “solar parameters”. In Fig. 2 the allowed regions for $\theta_{12}$ and $\Delta m^2_{21}$
from analyses of solar and KamLAND data are shown. Details of our solar
neutrino analysis can be found in Ref. [1] and references therein. We use the
same data as in Ref. [2] from the Homestake, SAGE, GNO, and Super-K ex-
periments [5], and the SNO day-night spectra from the pure D$_2$O phase [6],
but the CC, NC, and ES rates from the SNO salt-phase are updated accord-
ing to the latest 2005 data [7]. For the KamLAND analysis we are using the data equally binned in $1/E_{pr}$ ($E_{pr}$ is the prompt energy deposited by the positron), and we include earth matter effects and flux uncertainties following Ref. [15] (see the appendix of Ref. [2] for further details). We observe from the figure a beautiful agreement of solar and KamLAND data. Moreover, the complementarity of the two data sets allows a rather precise determination of the oscillation parameters: The evidence of spectral distortion in KamLAND data provides a strong constraint on $\Delta m^2_{21}$, and leads to the remarkable precision of $4\%$ at $1\sigma$ (compare Table I). As visible in the right panel of Fig. 2, alternative solutions around $\Delta m^2_{21} \sim 2 \times 10^{-4}$ eV$^2$ ($\sim 1.4 \times 10^{-5}$ eV$^2$), which are still present in the KamLAND-only analysis at $99\%$ C.L., are ruled out from the combined KamLAND+solar analysis at about $4\sigma$ ($5\sigma$). In contrast to $\Delta m^2_{21}$, the determination of the mixing angle is dominated by solar data. Especially recent results from the SNO experiment provide a strong upper bound on $\sin^2 \theta_{12}$, excluding maximal mixing at more than $5\sigma$.

The bound on $\theta_{13}$. For the third mixing angle currently only an upper bound exists. This bound is dominated by the CHOOZ reactor experiment [10], in combination with the $\Delta m^2_{31}$-determination from atmospheric and K2K experiments. However, recent improved data of solar and KamLAND experiments lead to a non-negligible contribution of these experiments to the global bound, especially for low values of $\Delta m^2_{31}$ within the
present allowed range \[1\]. From the left panel of Fig. 3 one deduces the following limits at 90% C.L. \((3\sigma)\):

\[
\sin^2\theta_{13} < \begin{cases} 
0.029 (0.067) & \text{CHOOZ+atm+K2K,} \\
0.041 (0.079) & \text{solar+KamLAND,} \\
0.021 (0.046) & \text{global data.} 
\end{cases}
\]

In the right panel of Fig. 3 we illustrate how the combination of solar and KamLAND data leads to a non-trivial bound on \(\theta_{13}\). The allowed regions in the plane of \(\sin^2\theta_{12}\) and \(\sin^2\theta_{13}\) show the complementarity of the two data sets, which follows from the very different conversion mechanisms: vacuum oscillations at a baseline of order 180 km for KamLAND, and adiabatic MSW conversion inside the sun for solar neutrinos. For a further discussion see the appendix of Ref. \[2\] or Ref. \[16\].

### 3. Prospects for the coming ten years

In this section I discuss the potential of long-baseline experiments, from which results are to be expected within the coming ten years. The first results will be obtained by the conventional beam experiments MINOS and the CNGS experiments ICARUS and OPERA. Subsequent information might be available from new reactor experiments. We take as examples D-Chooz as a first stage experiment, and a generic second-generation experiment labeled
Reactor-II, which could be realized at sites in Brazil, China, Japan, Taiwan, or USA, see Ref. [21] for an overview. Towards the end of the anticipated time scale results from super-beam experiments T2K and NOνA could be available. The main characteristics of these experiments are summarized in Table II. For the simulation the GLoBES software [24] is used. Technical details and experiment descriptions can be found in Refs. [3, 4, 25]. In the following I discuss the expected improvement on the leading atmospheric parameters, and the sensitivity to $\theta_{13}$, the CP phase $\delta_{CP}$ and the type of the neutrino mass hierarchy. A discussion of prospects to improve the determination of the leading solar parameters can be found in Ref. [26].

### TABLE II

Summary of upcoming experiments.

| Label                  | $L$     | $\langle E_{\nu} \rangle$ | $t_{\text{run}}$ | channel          |
|------------------------|---------|----------------------------|-------------------|------------------|
| **Conventional beam experiments:** |         |                            |                   |                  |
| MINOS [17]             | 735 km  | 3 GeV                      | 5 yr              | $\bar{\nu}_{\mu} \rightarrow \nu_{\mu}, \nu_{e}$ |
| ICARUS [18]           | 732 km  | 17 GeV                     | 5 yr              | $\nu_{\mu} \rightarrow \nu_{e}, \nu_{\mu}, \nu_{\tau}$ |
| OPERA [19]            | 732 km  | 17 GeV                     | 5 yr              | $\nu_{\mu} \rightarrow \nu_{e}, \nu_{\mu}, \nu_{\tau}$ |
| **Reactor experiments with near and far detectors:** |         |                            |                   |                  |
| D-Chooz [20]          | 1.05 km | $\sim$ 4 MeV               | 3 yr              | $\bar{\nu}_{e} \rightarrow \bar{\nu}_{e}$ |
| Reactor-II [21]      | 1.70 km | $\sim$ 4 MeV               | 5 yr              | $\nu_{e} \rightarrow \bar{\nu}_{e}$ |
| **Off-axis super-beams:** |         |                            |                   |                  |
| T2K [22]              | 295 km  | 0.76 GeV                   | 5 yr              | $\nu_{\mu} \rightarrow \nu_{e}, \bar{\nu}_{\mu}$ |
| NOνA [23]            | 812 km  | 2.22 GeV                   | 5 yr              | $\nu_{\mu} \rightarrow \nu_{e}, \nu_{\mu}$ |

The “atmospheric parameters”. In Fig. 4 I show how the upcoming experiments will improve the accuracy on $|\Delta m_{31}^2|$ and $\sin^2 \theta_{23}$. Already MINOS will decrease significantly the error on $|\Delta m_{31}^2|$. The non-trivial constraint on $|\Delta m_{31}^2|$ from the CNGS experiments results from the fact that in this analysis also the $\nu_{\mu}$ disappearance channel is included for these experiments (see Ref. [4] for details). For not too small values of $|\Delta m_{31}^2|$ T2K will provide a determination of order 2% at 2$\sigma$, which corresponds roughly to an improvement of one order of magnitude with respect to the present error. However, from the right panel of Fig. 4 one observes that for most values of $|\Delta m_{31}^2|$ T2K will improve the accuracy on $\sin^2 \theta_{23}$ only by a factor of 2 with respect to the present uncertainty. The main reason for this only modest improvement comes from the fact that disappearance experiments measure $\sin^2 2\theta_{23}$, and a small uncertainty on $\sin^2 2\theta_{23}$ translates into a relatively large error for $\sin^2 \theta_{23}$, if $\theta_{23}$ is close to maximal mixing.
Fig. 4. Prospective relative errors at 2\(\sigma\) on \(|\Delta m^2_{31}|\) (left) and \(\sin^2 \theta_{23}\) (right) as a function of the true value of \(\Delta m^2_{31}\) and for the true value \(\sin^2 \theta_{23} = 0.5\). The dots with the error bars indicate the present accuracy at 2\(\sigma\) from atmospheric and K2K data. The gray shaded region is excluded at 3\(\sigma\) by present data.

It is interesting to note that the lower bound on \(|\Delta m^2_{31}|\) from NO\(\nu\)A is comparable to the one from T2K, however, the upper bound is significantly weaker because of a strong correlation between \(|\Delta m^2_{31}|\) and \(\sin^2 \theta_{23}\). Also the \(\sin^2 \theta_{23}\) measurement of NO\(\nu\)A is affected by this correlation, which gets resolved only in the range \(|\Delta m^2_{31}| \gtrsim 3 \times 10^{-3} \text{ eV}^2\). This correlation appears because the NO\(\nu\)A detector is optimized for electrons, whereas the atmospheric parameters are determined essentially by the \(\nu_\mu\) disappearance channel. Let me add that as in Ref. [4] we assume here a low-Z-calorimeter. Using the totally active scintillator detector (TASD) as proposed in Ref. [23] improves the performance of NO\(\nu\)A for the atmospheric parameters.

The limit on \(\theta_{13}\). Fig. 5 shows the limits which can be obtained on \(\sin^2 2\theta_{13}\) by the experiments under consideration, if no signal for a finite \(\theta_{13}\) is found. One observes that the conventional beams may improve the present limit roughly by factor of 2, D-Chooz by a factor of 4, and the super-beams by a factor of 6. An optimized reactor experiment could improve the present bound by more than one order of magnitude, reaching a limit for \(\sin^2 2\theta_{13}\) below 10\(^{-2}\) at 90\% C.L. The limits shown in Fig. 5 depend on the true value of \(\Delta m^2_{31}\); in general stronger limits can be reached for larger values of \(\Delta m^2_{31}\).

The figure illustrates that the \(\sin^2 2\theta_{13}\) limits from \(\nu_\mu \rightarrow \nu_e\) appearance beam experiments are strongly affected by correlations, mainly between \(\sin^2 2\theta_{13}\) and \(\delta_{\text{CP}}\). The bars labeled “Degeneracies” originate from the fact that the hierarchy cannot be determined, and the sensitivity is quoted for
the hierarchy which gives the worse limit (see the appendix of Ref. [4] for a detailed discussion of the sensitivity limit). Clearly, the $\sin^2 2\theta_{13}$-limit from reactor experiments is completely free from correlations and degeneracies [3, 27], since the $\bar{\nu}_e$ survival probability does not depend on $\delta_{CP}$ and $\theta_{23}$, and the dependence on the solar parameters is negligibly small. These experiments are dominated by systematical uncertainties, related mainly to the comparison of the near and far detectors. A possibility to reduce significantly the impact of these uncertainties has been presented in Ref. [28].

![Graph showing sensitivity limits for various experiments.](image)

Fig. 5. Sensitivity to $\sin^2 2\theta_{13}$ at 90% C.L. The left edges of the bars are obtained for the statistics limits only, whereas the right edges are obtained after successively switching on systematics, correlations, and degeneracies, i.e., they correspond to the final sensitivity. The gray shaded region is excluded at 90% C.L. by present data. For the true values of the oscillation parameters, we use $\Delta m^2_{31} = +2.0 \times 10^{-3}$ eV$^2$, $\sin^2 2\theta_{23} = 1$, $\Delta m^2_{21} = 7.0 \times 10^{-5}$ eV$^2$, $\sin^2 2\theta_{12} = 0.8$.

**Possibilities for large $\theta_{13}$.** Finally I discuss the potential of the experiments of Table II if $\theta_{13}$ is not too far from the present upper bound. In Fig. 6 the allowed regions in the $\sin^2 2\theta_{13}$-$\delta_{CP}$ plane are shown assuming a true value of $\sin^2 2\theta_{13} = 0.1$. For the super-beam experiments T2K and NO$\nu$A one observes the strong correlation between $\sin^2 2\theta_{13}$ and $\delta_{CP}$, which introduces a large uncertainty in $\sin^2 2\theta_{13}$ but does not permit to draw any conclusions on $\delta_{CP}$. In contrast, the reactor experiment provides an accurate measurement of $\sin^2 2\theta_{13}$ with an accuracy at the level of 10% at 90% C.L. None of the experiments on its own can identify the mass hierarchy. As indicated in the figure, the best fit point of the wrong hierarchy is as good as the true best fit point. However, from the combination of T2K+NO$\nu$A+Reactor-II the wrong hierarchy can be disfavored with $\Delta \chi^2 = 3.1$, which corresponds roughly to the 90% C.L. The crucial ele-
ment for the mass hierarchy determination is the long baseline of 812 km for NO\(\nu\)A, leading to matter effects which allow to distinguish between normal and inverted hierarchy. Let me add, that the hierarchy sensitivity strongly depends on the true value of \(\delta_{\text{CP}}\); typically it is optimal for \(\delta_{\text{CP}} \simeq -90^\circ\), and worst for \(\delta_{\text{CP}} \simeq 90^\circ\) [4].

As visible from Fig. 6 no information can be obtained on CP violation, i.e., at least one of the CP-conserving values \(\delta_{\text{CP}} = 0, 180^\circ\) is contained within the 90\% C.L. region, even though the assumed true value \(\delta_{\text{CP}} = 90^\circ\)

![](image)

Fig. 6. The 90\% C.L. (solid) and 3\(\sigma\) (dashed) allowed regions (2 d.o.f.) in the \(\sin^2 2\theta_{13}\)–\(\delta_{\text{CP}}\) plane for the true values \(\sin^2 2\theta_{13} = 0.1\) and \(\delta_{\text{CP}} = 90^\circ\). The black curves refer to the allowed regions for the normal mass hierarchy (assumed to be the true hierarchy), whereas the gray curves refer to the \(\text{sgn}(\Delta m^2_{31})\)-degenerate solution (inverted hierarchy), where the projections of the minima onto the \(\sin^2 2\theta_{13}\)–\(\delta_{\text{CP}}\) plane are shown as diamonds (normal hierarchy) and triangles (inverted hierarchy). For the latter, the \(\Delta \chi^2\)-value with respect to the best-fit point is also given.
corresponds to maximal CP violation. The reason is that no anti-neutrino data is included in this analysis, since due to the low cross sections it seems unlikely that significant anti-neutrino data will be available within the anticipated time scale. Note however, that from the combined analysis some values of $\delta_{\text{CP}}$ can be excluded for a given mass hierarchy.

4. Conclusions

I have reviewed the present status of neutrino oscillations from world neutrino oscillation data, including solar, atmospheric, reactor and accelerator experiments. The results of a global analysis within the three-flavor framework have been presented, and in particular, the bound on $\theta_{13}$, which emerges from the interplay of various data sets has been discussed. Furthermore, a prospect on where we could stand in neutrino oscillations in ten years from now has been given. Based on a simulation of upcoming long-baseline accelerator and reactor experiments the improvements on the leading atmospheric parameters, as well as the sensitivity to $\theta_{13}$, $\delta_{\text{CP}}$ and the neutrino mass hierarchy have been discussed.

I thank the organizers for the very pleasant and interesting conference. The results presented here have been obtained in collaboration with P. Huber, M. Lindner, M. Maltoni, M. Rolinec, M.A. Tórtola, J.W.F. Valle and W. Winter. T.S. is supported by the Marie Curie Intra-European Fellowship within the 6th European Community Framework Program.
