Global passivity in microscopic thermodynamics

Raam Uzdin and Saar Rahav
Schulich Faculty of Chemistry, Technion - Israel Institute of Technology, Haifa, Israel

The main thread that links classical thermodynamics and the thermodynamics of small quantum systems is the celebrated Clausius inequality form of the second law. However, its application to small quantum systems suffers from two cardinal problems: (i) The Clausius inequality does not hold when the system and environment are initially correlated - a commonly encountered scenario in microscopic setups. (ii) In some other cases, the Clausius inequality does not provide any useful information (e.g. in dephasing scenarios). We address these deficiencies by developing the notion of global passivity and employing it as a tool for deriving thermodynamic inequalities on observables. For initially uncorrelated thermal environments the global passivity framework recovers the Clausius inequality. More generally, global passivity provides an extension of the Clausius inequality that holds even in the presences of strong initial system-environment correlations. Crucially, the present framework provides additional thermodynamic bounds on expectation values. To illustrate the role of the additional bounds we use them to detect unaccounted heat leaks and weak feedback operations (“Maxwell’s demons”) that the Clausius inequality cannot detect. In addition, it is shown that global passivity can put practical upper and lower bounds on the buildup of system-environment correlation for dephasing interactions. Our findings are highly relevant for experiments in various systems such as ion traps, superconducting circuits, atoms in optical cavities and more.

I. INTRODUCTION

Recent years have seen a surge of interest in the thermodynamics of small systems. Classical thermodynamics was developed for macroscopic systems that are weakly coupled to large environments. Technological advances now allow studying various processes in nanoscopic systems and it is of great interest to understand such processes from a thermodynamic point of view.

Applying thermodynamics to processes in small systems requires going beyond the assumptions and methodologies used in classical thermodynamics for several reasons: (1) The dynamics of microscopic systems is quantum and questions regarding the thermodynamic role of quantum coherence, entanglement, and measurements become important; (2) The system-environment coupling cannot generally be assumed to be weak. As a result the environment is modified by the system, and strong recurrences may take place; (3) A non-negligible degree of initial system-environment correlation may be present, leading to effects such as heat flow from a cold subsystem to a hot one [1, 2]; (4) Small quantum systems are easily taken out of equilibrium and therefore their dynamics cannot be efficiently described by small number of quantities such as volume, average energy and so on. In summary, it is of great interest to try to adapt thermodynamics to deal with some of these deviations from the assumptions used in classical macroscopic thermodynamics.

Several theoretical advances that extend thermodynamics were developed in the last few decades. Stochastic thermodynamics [3, 4] describes the fluctuations in thermodynamic characteristics of a process such as heat and work. These were found to satisfy the celebrated fluctuation theorems [5, 6], a family of equalities that also hold far from equilibrium. Thermodynamic resource theory [7, 10] studies the possible transformations a system can undergo by interacting with a thermal bath. Both theories have their limitations. Stochastic thermodynamics consider either systems decoupled from the environment or systems coupled to macroscopic environments that remain in equilibrium during the process. Resource theory is limited to a specific set of operations called “thermal operations”.

The interest in the thermodynamics of small systems has led to several experimental realizations of microscopic processes that take after macroscopic thermodynamics. A heat engine with a single ion as a working fluid [11], as well as a three-ion absorption refrigerator [12] have been implemented. Algorithmic cooling [13] has been demonstrated in NMR [14]. In addition, quantum features of heat machines have also been recently observed in NV centers in diamonds [15]. An experiment demonstrating the thermodynamic role of initial correlations was done in NMR [2]. While these experiments verify the validity of the second law for the smallest quantum systems, they also offer the possibility of testing new thermodynamic predictions such as the ones suggested in this paper.

In this work, we will mostly be interested in processes where a small system of interest is coupled to other small systems that act as environments. As a starting point the small environments are assumed to be initially in Gibbs states \( \rho_0^{(i)} = \exp(-\beta_i H_i)/\text{tr}[\exp(-\beta_i H_i)] \), where \( H_i \) is the Hamiltonian of environment \( i \) and \( \beta_i \) is its inverse temperature. The system of interest can start in any state. Due to the microscopic size of the small environments, the interaction with the system will in general modify them, and they can substantially deviate from their initial Gibbs state. Moreover, they may develop a strong correlation to the system of interest. We call such small and initially thermal environments ‘microbaths’ to distinguish them from macroscopic baths encountered in classical thermodynamics.

The dynamics of the whole setup containing the sys-
tem of interest and all the microbaths is described by a global unitary dynamics (quantum evolution). More generally the dynamics can be described by a statistical mixture of unitaries. Physically, a mixture of unitaries corresponds to the scenario where there is some noise in the controls generating the thermodynamic protocol. These global unitaries act on both the system and the microbaths (leading to heat flows), and can also do work. Our goal is to describe the thermodynamics of such processes even when the elements are initially correlated to each other.

One of the characteristics of thermodynamics is the appearance of inequalities. The second and third laws tell us that there are tasks that cannot be done. In the current setup the most relevant form of the second law is the Clausius inequality (CI). In the following, we show that the concepts of passivity [16–20] can be extended and be used to derive additional inequalities. These inequalities have several appealing features not exhibited by the CI: (1) they hold for systems that have some initial quantum or classical correlation to the environment; (2) They can set upper and lower bounds on the system-environment correlation buildup; (3) They allow to derive families of inequalities that can detect external tempering in the form of heat leaks or feedback (e.g., a Maxwell demon) even when the CI fails to detect the feedback.

The flexibility and general applicability of the global passivity framework presented in this work come at a price. Global passivity connects the initial state of the setup to the observable appearing in the resulting inequalities. As a result, in some cases the predictions obtained from these inequalities may involve non-intuitive observables. Nevertheless, the examples we give in this paper demonstrate that one can derive interesting new predictions in various important scenarios that were so far outside the scope of the thermodynamic description. We believe that the flexibility of this framework is useful, and will lead to additional predictions on measurable quantities in nanoscopic setups.

In Sec. II we introduce the notion of global passivity and use it to derive a version of the Clausius inequality that is valid in the presence of initial system-environment correlation. Several important examples are studied in detail. Section III uses the concept of global passivity to obtain a new type of inequalities. We exemplify the use of these new inequalities for detecting unaccounted heat leaks, for detecting the presence of “lazy” Maxwell demons, and for studying the buildup of system-environment correlation in a dephasing scenario. In these examples, the results obtained from global passivity are much more useful compared to the standard second law. We summarize our findings in Sec. IV.

II. EXTENDING THE CLAUSIUS INEQUALITY USING GLOBAL PASSIVITY

In this the section, we introduce the notion of global passivity and demonstrate how it can be used to derive various thermodynamic inequalities. Before doing so, we present the celebrated Clausius inequality formulation of the second law of thermodynamics. Under some restrictions, this formulation holds in some microscopic setups. We discuss its structure and its limitations when applied to microscopic systems.

A. The Clausius inequality in microscopic setups

Historically the second law was developed for macroscopic systems such as steam engines and large thermal reservoirs. However, it turns out that under some conditions one of its formulations, the Clausius inequality (CI) also holds for small quantum systems interacting with each other and with external fields. Since this corresponds to the setup considered in this paper, the CI will serve as a natural reference for the new results described in this article.

Consider a setup in which a system of interest and several other small systems are prepared in an initially
uncorrelated state of the form
\[ \rho_0^{\text{tot}} = \rho_0^{\text{sys}} \otimes e^{-\beta_1 H_1} \otimes ... e^{-\beta_N H_N} / Z_0, \tag{1} \]
where \( Z_0 = \text{tr}[e^{-\sum_{i=1}^N \beta_i H_i}] \) is a normalization factor, \( H_i \) are the Hamiltonians of the systems that act as microbaths, where \( \beta_i \) corresponds to the initial inverse temperatures. A thermodynamic process is realized via some time-dependent global Hamiltonian that acts on all elements (not necessarily simultaneously). As a result, the setup evolves unitarily in time. The initial preparation distinguishes the system of interest, which can be in any initial state, from the microbaths that are initially in a thermal state. We note that this initial state is special due to the lack of correlation between the different elements.

The process described above satisfies a quantum-microscopic version of the CI [21,23],
\[ \Delta S^{\text{sys}} + \sum_k \beta_k q_k^{\text{bath}} \geq 0, \tag{2} \]
where \( q_k = \Delta \langle H_k \rangle \) is the change in the average energy of microbath \( k \). \( \Delta S^{\text{sys}} = S(\rho_f^{\text{sys}}) - S(\rho_0^{\text{sys}}) \) is the change in the von Neumann entropy of the system \( S^{\text{sys}}(\rho^{\text{sys}}) \doteq -\text{tr}[\rho^{\text{sys}} \ln \rho^{\text{sys}}] \) where \( \rho^{\text{sys}} = \text{tr}_{\text{baths}}[\rho^{\text{tot}}] \). This microscopic version goes beyond the assumptions of classical thermodynamics since the microbaths can be arbitrary small in size and be driven far from equilibrium during the process. However, it is restricted by the demand that all the elements are uncorrelated and that the microbaths start in thermal state.

One of the goals of this paper is to generalize [2] to the case where the elements are initially correlated. To make sure we find a plausible generalization we now take a closer look at the structure of the CI. The first term deals with changes in a quantity that is nonlinear in the density matrix \( S(\rho) = -\text{tr}[\rho \ln \rho] \). The non linearity appears both in the initial and the final state. As such, it is not an observable that can be directly measured, but rather a quantity that is calculated after \( \rho \) has been evaluated via tomography of the system. Nevertheless, its informational interpretation makes it very useful. The second term \( \sum_k \beta_k q_k^{\text{bath}} \) is a measurable quantity that describes changes in expectation values.

With this combination of system information and observables, the CI neatly expresses the energy-information relation that appears in fundamental processes such as Landauer’s erasure, Szilard engine, and reversible state preparation [24, 25]. When extending the CI it is desirable to maintain this information-expectation value structure. See [25] for an extension of the second law that preserves the information-observable structure, and [9, 11] for an extension that does not.

Finally, we point out that using [1] and \( \rho_0^{\text{env}} \doteq \text{tr}_{\text{sys}} \rho_0^{\text{tot}} \), the term \( \sum_k \beta_k q_k^{\text{bath}} \) can be written as \( \text{tr}[(\rho_f^{\text{env}} - \rho_0^{\text{env}})(-\ln \rho_0^{\text{env}})] \). Using the notation
\[ B^{\text{env}} = -\ln \rho_0^{\text{env}}, \tag{3} \]
the standard CI [2] can be written in a form that will be useful later
\[ \Delta S^{\text{sys}} + \Delta \langle B^{\text{env}} \rangle \geq 0. \tag{4} \]

B. Passivity and expectation values inequalities
Passivity [16, 19, 26, 27] is defined as follows: a time-independent operator \( A \) and a density matrix \( \rho \) are said to be passive w.r.t. each other if (i) \( \rho \) and \( A \) are diagonal in the same basis (same eigenvectors). (ii) in a basis sorted in increasing order of eigenvalues of \( A \), the eigenvalues of \( \rho \) are decreasing. Since the eigenvalues of \( \rho \) correspond to probabilities it implies that when measuring \( A \) in a system prepared in a passive state, higher eigenvalues of \( A \) are less probable to be observed than lower eigenvalues. This is illustrated in Fig. 2a.

Passive pairs \( \{A, \rho_A\} \) satisfy an important inequality. Consider an initial passive state \( \rho_A \) w.r.t \( A \) that is mapped to a final state via a unitary transformation
\[ \rho_f = U \rho_A U^\dagger, \tag{5} \]
more generally by a mixture of unitaries
\[ \rho_f = \sum_k p_k U_k \rho_A U_k^\dagger, \tag{6} \]
where \( p_k \) denotes the probability of executing the unitary \( U_k \). The passivity of the initial state ensures that the expectation value \( \langle A \rangle_f = \text{tr}(\rho_f A) \) satisfies
\[ \langle A \rangle_f \geq \langle A \rangle_{\text{pass}} = \text{tr}(\rho_A A). \tag{7} \]
Alternatively stated, the passive state gives the lowest expectation value achievable by mixture of unitaries transformations. The validity for mixture of unitaries follows from linearity and the validity for any single unitary [5]. To see why (7) holds for any unitary we use the fact that when a unitary operates on a diagonal matrix then it holds that \( \rho_f \), the diagonal elements of the new density matrix, are related to the original diagonals \( \rho_0 \) via a mixture of permutations \( \Pi_k \) that are executed with some probability \( \zeta_k \): \( \rho_f = \sum_k \zeta_k \Pi_k \rho_0 \). When the initial distribution is passive w.r.t to \( A \), \( \rho_0 = \rho_{\text{pass}} \), any permutation or a mixture of permutations (doubly stochastic map) will increase the expectation value of \( A \) (Fig. 2b). Alternatively, one can use the proof presented in Ref. [13].

Traditionally in thermodynamics, the passivity inequality is related to the amount of work that can be extracted from a system using a transient unitary operation on the system. That is, the Hamiltonian of the system is driven by some external fields for some time, but in the end it returns to its original value (cyclic Hamiltonian). This maximum extractable work is called the
These three differences lead to a new connection between for any operator \( A \). In contrast, in this paper we ask (3) In traditional passivity the operator (the Hamiltonian) heat flows between the elements. 2) We apply work extraction from a specific element in the setup. In this paper to obtain additional inequalities on expectation values of observables.

The first extension concerns operators which are not passive with respect to the initial state. Let \( \rho_f \) be density matrix obtained from \( \rho_0 \) by a mixture of unitaries. We are interested in the change of the expectation value of an operator \( \hat{A} \). Even when the operator of interest \( \hat{A} \) and the initial state \( \rho_0 \) are not passive with respect to each other we can write

\[
\Delta \langle \hat{A} \rangle = \langle \hat{A} \rangle_f - \langle \hat{A} \rangle_0 \\
\geq \langle \hat{A} \rangle_{\min} - \langle \hat{A} \rangle_0 ,
\]

where \( \langle \hat{A} \rangle_{\min} \) is the minimal expectation value of \( \hat{A} \) obtained by transforming \( \rho_0 \) via a mixture of unitaries. From the definition of passive states it holds that

\[
\langle \hat{A} \rangle_{\min} = tr[\rho_{\hat{A} \text{pass}} \hat{A}] = \langle \hat{A} \rangle_{\hat{A} \text{pass}}
\]

where \( \rho_{\hat{A} \text{pass}} \) is obtained from \( \rho_0 \) via a unitary rotation \( V \) so that \( \rho_{\hat{A} \text{pass}} \) is passive with respect to \( \rho_{\hat{A} \text{pass}} \). Therefore, we obtain

\[
\Delta \langle \hat{A} \rangle \geq \langle \hat{A} \rangle_{\hat{A} \text{pass}} - \langle \hat{A} \rangle_0
\]

Importantly, the right hand side is independent of \( \rho_f \). Thus, it can be evaluated before running the experiment without knowing the details of the evolution. As shown in Sec. IIIIC Eq. (11) can be quite useful.

The second extension of passivity we exploit in this paper concerns the case where a passive operator with respect to the initial density matrix is given, and we want to find additional passive operators in order to set additional constraints on additional observable quantities. Let \( \hat{A} \) be a passive operator w.r.t. to \( \rho_0 \), and \( g \) be an analytic and monotonically increasing function in the interval between the smallest and largest eigenvalues of \( \hat{A} \). It holds that the operator \( g(\hat{A}) \) is also passive w.r.t. \( \rho_0 \) and therefore

\[
\Delta \langle g(\hat{A}) \rangle \geq 0
\]

for any mixture of unitaries. As will be demonstrated later these new inequalities are not just restatement of (8) and they have different physical content. The proof of (12) immediately follows from the fact that \( \hat{A} \) and \( g(\hat{A}) \) have the same eigenvectors and also the same eigenvalue ordering since monotonically increasing functions just “stretches” the spectrum (Fig. 2c) but do not change the order of the eigenvalues. As a result, any density matrix \( \rho_0 \) that is passive with respect to \( \hat{A} \) is also automatically passive with respect to \( g(\hat{A}) \).
C. Global passivity and its relation to Clausius inequality

To introduce the notion of global passivity and its relation to the second law we first examine a simplified scenario. In the next subsection we treat the general case. Consider a setup that includes only initially uncorrelated microbaths. That is, there is no system that is initially in a non thermal state. The initial state of the whole setup is therefore given by

\[ \rho_0^{\text{tot}} = e^{-\beta_1 H_1} \otimes \ldots e^{-\beta_N H_N} / Z_0, \tag{13} \]

where \( Z_0 = \text{tr}[e^{-\beta_1 H_1} \otimes \ldots e^{-\beta_N H_N}] \) is a normalization factor. This situation can describe an absorption refrigerator such as the one implemented in \cite{12}. In this case the CI reduces to

\[ \sum_k \beta_k q_k^{\text{bath}} \geq 0. \tag{14} \]

To apply passivity for this setup we look for operators that are passive with respect to \( \rho_0^{\text{tot}} \). A simple and systematic way to achieve this is to use \( \rho_0^{\text{tot}} \) for the construction of the passive operators. We start with the elementary choice

\[ B^{\text{tot}} = -\ln \rho_0^{\text{tot}}. \tag{15} \]

We emphasize that \cite{15} defines a time-independent operator based on the initial state. In particular, the expectation value of this operator at time \( t \), reads \( \langle B^{\text{tot}} \rangle = \text{tr}[\rho^{\text{tot}}(t)(-\ln \rho_0^{\text{tot}})] \). It is simple to verify that \( B^{\text{tot}} \) is \( \rho_0^{\text{tot}} \) passive. By inverting \cite{15} we get \( \rho_0^{\text{tot}} = e^{-B^{\text{tot}}} \) that immediately implies that larger eigenvalues of \( B \) are associated with lower probabilities.

Next, the setup evolves by a global unitary or mixture of unitaries

\[ \rho_f^{\text{tot}} = \sum_k p_k U_k \rho_0^{\text{tot}} U_k^\dagger. \tag{16} \]

From passivity of \( B^{\text{tot}} \) w.r.t. \( \rho_0^{\text{tot}} \) we get the inequality

\[ \Delta \langle B^{\text{tot}} \rangle \geq 0. \tag{17} \]

For the specific initial state \cite{13}, \( B^{\text{tot}} = \beta_k H_k - (\ln Z_0) I \) where \( I \) is the identity operator. As a result \cite{17} becomes \( \sum_k \beta_k q_k \geq 0 \), and we retrieve the result predicted from the CI for this setup.

As mentioned earlier, we call this approach global passivity since we apply passivity for the whole setup and not just to the system of interest. In standard passivity, the operator is fixed (The Hamiltonian of the system) and the quantity of interest is the passive state. Here the state is fixed/given by the initial preparation of the setup, and we are interested in operators that are passive with respect to it. In that sense, the present approach is complementary to the one usually used in the literature on passivity \cite{16,19,20,27}.

The global passivity inequality \cite{17} is valid also for a setup that includes a system with an arbitrary initial state \cite{1}. The resulting inequality is less tight than the CI. On the other hand, it involves quantities that are easier to evaluate since all quantities are linear in the final density matrix. Hence there is no need to perform a full system tomography in order to evaluate \( S^{\text{sys}}(\rho_f) \) which appears in the CI. Details can be found in Appendix I.

Next, to obtain the complete CI form \cite{3} that include the system entropy term, we introduce the passivity-divergence relation. Quite remarkably we obtain that the passivity-divergence relation not only reproduces the full CI but also yields a version of the CI that is valid in the presence of initial system-environment correlation.

D. The passivity-divergence relation and the correlation compatible Clausius inequality

In thermal machines and in various thermal processes (e.g. thermal state preparation \cite{24}) there is often a system of interest that does not start in a thermal state. In such cases, the inequality \cite{14} is not applicable and \cite{2} has to be used. We now show to use a more powerful version of global passivity to obtain an inequality that distinguishes between a system and its environment. We emphasize that this is not just a re-derivation of the CI since the inequality we obtain can handle initial correlation between the system and the environment (in contrast to the CI).

Let us consider a setup initially prepared in a state \( \rho_0^{\text{tot}} \). In contrast to the assumption of lack of correlation between the system of the environment \cite{1} we now allow for a general density matrix \( \rho_0^{\text{tot}} \) that may contain classical and quantum correlation between the various elements of the setup. The initial reduced state of the system is obtained by tracing out the environment \( \rho_0^{\text{sys}} = \text{tr}_{\text{env}} \rho_0^{\text{tot}} \). Similarly the initial state of the environment is \( \rho_0^{\text{env}} = \text{tr}_{\text{sys}} \rho_0^{\text{tot}} \).

Our starting point is the following identity

\[ \text{tr}[(\rho_2 - \rho_1)(-\ln \rho_1)] \equiv S(\rho_2) - S(\rho_1) + D(\rho_2|\rho_1), \tag{18} \]

where

\[ D(\rho_2|\rho_1) = \text{tr}[\rho_2(\ln \rho_2 - \ln \rho_1)] \geq 0, \tag{19} \]

is the quantum relative entropy. To connect it to the notion of global passivity we set \( \rho_2 = \rho_f^{\text{tot}}, \rho_1 = \rho_0^{\text{tot}} \equiv \exp(-B^{\text{tot}}) \) in \cite{18} and obtain

\[ \Delta \langle B^{\text{tot}} \rangle = \Delta S^{\text{tot}} + D(\rho_f^{\text{tot}}|\rho_0^{\text{tot}}). \tag{20} \]

We now focus on the first term in the right hand side that describes the change of the total von Neumann entropy of the setup. If the evolution of the setup is given by an exact unitary transformation \( \rho_f^{\text{tot}} = U \rho_0^{\text{tot}} U^\dagger \) then

\[ \Delta S^{\text{tot}} = S(\rho_f^{\text{tot}}) - S(\rho_0^{\text{tot}}) = 0 \tag{23}. \]

When a mixture of unitaries \cite{16} is applied to the setup, it holds that
\( \Delta S^{\text{tot}} \geq 0 \). This follows from the fact that the von Neumann entropy is Schur concave \( [29] \), and \( \rho_0^{\text{tot}} \) majorizes \( \rho_f^{\text{tot}} \) (the majorization follows immediately from \( [16] \)). Physically, a mixture of unitaries describes the dynamics in the presence of some noise/randomness in the protocol.

Using \( \Delta S^{\text{tot}} \geq 0 \) in \( [20] \) we obtain the passivity-divergence relation

\[
\Delta \langle B^{\text{tot}} \rangle \geq D(\rho_f^{\text{tot}} | \rho_0^{\text{tot}}).
\]

\( (21) \)

Since \( D(\rho_f^{\text{tot}} | \rho_0^{\text{tot}}) \geq 0 \), the passivity divergence relation \( (21) \) immediately implies the global passivity \( \Delta \langle B^{\text{tot}} \rangle \geq 0 \). This is alternative proof of the global passivity inequality.

Relation \( (21) \) is expressed using quantities that involve the whole setup. To derive an inequality that distinguishes between system and environment and has a clear connection to the CI we use a property of the quantum relative entropy: the quantum relative entropy decreases when subsystems are traced out \( [30] \). In particular, it holds that

\[
D(\rho_f^{\text{tot}} | \rho_0^{\text{tot}}) \geq D(\rho_f^{\text{sys}} | \rho_0^{\text{sys}})
\]

\( (22) \)

for any \( \rho_f^{\text{tot}}, \rho_0^{\text{tot}} \) (even if the system is correlated to the rest of the setup). As a result we get

\[
\Delta \langle B^{\text{tot}} \rangle \geq D(\rho_f^{\text{sys}} | \rho_0^{\text{sys}}).
\]

\( (23) \)

Applying \( (18) \) to the system density matrix and using it in \( (23) \), we obtain the Correlation (compatible) Clausius Inequality (CCI)

\[
\Delta S^{\text{sys}} + \Delta \langle B^{\text{tot}} \rangle - \langle B^{\text{sys}} \rangle \geq 0,
\]

\( (24) \)

where \( B^{\text{sys}} \) is defined as

\[
B^{\text{sys}} = -\ln \rho_0^{\text{sys}}.
\]

The CCI immediately reduces to the CI when the system and the environment are initially uncorrelated since in this case \( \langle B^{\text{tot}} \rangle - \langle B^{\text{sys}} \rangle = \langle B^{\text{env}} \rangle \). The CCI \( (24) \) is one of the main results in this paper. We use the terminology correlation compatible Clausius inequality for two reasons. Firstly, it reduces to the CI when \( \rho_0^{\text{tot}} = \rho_0^{\text{sys}} \otimes \rho_0^{\text{env}} \). Secondly, the CCI has the same structure of the CI: it relates changes in the von Neumann entropy of the system of interest and changes in expectation values. The difference is that on top of the changes in the environment expectation values, there is also a change in expectation value related to the initial system-environment correlation.

The CCI can also be recast in a slightly different form

\[
\Delta S^{\text{sys}} + \Delta \langle B^{\text{env}} \rangle + \Delta \langle B^{\text{corr}} \rangle \geq 0
\]

\( (25) \)

where \( B^{\text{corr}} \) is an Hermitian operator that identically vanishes when the system and environment are initially uncorrelated. As the other \( B \) operators, \( B^{\text{corr}} \) is a time-independent operator that is determined by \( \rho_0^{\text{tot}} \).

There is a ‘price’ for incorporating the initial sys-env correlation into the second law in the form of expectation values. For the same initial reduced state of the environment, the form of \( B^{\text{corr}} \) will depend on the initial correlations in \( \rho_0^{\text{tot}} \). That is, for different correlations, different expectation values appear in the CCI. To put this ‘price’ in perspective, it is important to note that the relation between the initial state of the setup and the expectation values that appears in the CCI is already present in the standard CI. The initial preparation of the environment in Gibbs states leads to the \( \sum_k \beta_k q_k \) term in the CI. In the CCI we get that not only the initial state of the environment determines the expectation values but also the correlation to the system.

The role of the new correlation operator can be experimentally studied in various experimental setups such as ion traps, superconducting qubits and more. One of the simplest physical scenarios where this term strongly manifests is heat flow between two initially correlated spins. This has recently experimentally demonstrated with NMR spins with quantum correlation \( [2] \). The quantum correlation of the initial state manifests in non-zero geometric quantum discord. The initially colder spin (‘c’), will constitute the system and the initially hotter (‘h’) will constitute the environment. Due to the initial correlation heat can flow from the cold spin to the hot spin and make the cold spin colder and the hot spin hotter.

To test the CCI we use the experimental parameters of \( [2] \) and plot (Fig. 3b) the CI accumulated entropy production: \( \Delta S^c + \beta q_h \) and the LHS of the CCI \( \Delta S^c + 2 \beta q_h + \Delta \langle B^{\text{corr}} \rangle \). When there is no initial correlation both expression are identical as shown in Fig. 3b. In the presence of correlation, the standard entropy production \( \Delta S^c + \beta q_h \) becomes negative as the CI no longer holds for this scenario. In contrast, the CCI expression \( \Delta S^c + \beta q_h + \Delta \langle B^{\text{corr}} \rangle \) remains positive at all times.

Finally we emphasize that the essence of the CCI is the inequality \( D(\rho_f^{\text{tot}} | \rho_0^{\text{tot}}) \geq D(\rho_f^{\text{sys}} | \rho_0^{\text{sys}}) \) and not \( \Delta S^{\text{tot}} \geq 0 \). \( \Delta S^{\text{tot}} > 0 \) is simply another layer of randomness that is externally added by the noise in the controls. By using low noise control devices, an experimentalist can ensure that the evolution is carried out by a single unitary to very high accuracy. We also point out that the CCI is a non-perturbative result and is valid for arbitrarily strong initial correlations and/or interactions between the elements.

In the next subsection, we study an important thermodynamic scenario and work out explicitly the various terms in the CCI. As side comment, we point out that the derivation above for the case \( \rho_0^{\text{tot}} = \rho_0^{\text{sys}} \otimes \rho_0^{\text{env}} \) constitutes an alternative to the previous derivations of the standard CI second law for microscopic quantum systems.
Let us consider a system that is permanently coupled to one of the small environments available in the setup. (a) In the presence of initial correlation \( C = 0 \), an energy conserving interaction makes the hot spin colder and the cold spin hotter. (c) In the presence of initial correlation \( C = -0.19 \), the same interaction makes the cold spin colder and the hot one hotter. All parameters are taken from a recent NMR experiment \([2]\). The top graph shows the CI “entropy production” (red) and the left hand side (l.h.s) of the CCI (blue) have the same values for this case and both are positive at all time. However in presence of initial correlation (bottom graph), the l.h.s. of the CCI attains negative values, and the CI fails. In contrast, the CCI remains valid (positive l.h.s.) at all times.

\[ \rho_0^{\text{tot}} = \frac{1}{Z_{hs} Z_{e}} e^{-\beta_h (H_h + H_{e} + H_{I})} e^{-\beta_e H_e} \]  

(27)

For this setup the CCI \([24]\) yields the following inequality

\[ \Delta S^{\text{sys}} + \beta_e q_e + \beta_h q_h + \beta_h \Delta \langle H_{I,0} \rangle + \Delta \langle H_s - H_s^{\text{eff}} \rangle \geq 0. \]  

(28)

As before \( q_e, q_h \) are the change in the average “bare” energies of the microbaths \( \langle H_e \rangle, \langle H_h \rangle \) and

\[ H_s^{\text{eff}} = -\frac{1}{\beta_h} \ln \rho_0^{\text{sys}} = -\frac{1}{\beta_h} \ln \text{tr}_{hs} e^{-\beta_h (H_s + H_{I,0} + H_h)} \]  

(29)

The quantity \( H_s^{\text{eff}} - H_s \) is known as the potential of means force \([32]\) or as the solvation potential \([33]\). The first three terms in \([25]\) are the “bare” terms that appear in the Clausius inequality. The fourth term \( \Delta \langle H_{I,0} \rangle \) originates from the CCI and it expresses the change in the interaction energy during the process. The last term in \([25]\) \( \Delta (H_s - H_s^{\text{eff}}) \) is the change in the “dressing energy” of the system. Due to the non-negligible interaction with the environment the system is not initially in the thermal state of the bare system Hamiltonian.

While this paper was reviewed it was brought to our attention that the CCI for the coupled thermal state has some similarity to a recent classical formulation of the second law \([33]\) for a very similar scenario. Despite the similarity there are quite a few differences between our result \([25]\), and \([33]\). We point out the two most important ones. First, our result is valid also in the presence of coherences (in the energy basis) and quantum correlations that arise from the initial system-environment coupling. Second, CI-like inequalities that are derived from fluctuation theorems \([34, 35]\) involve the equilibrium entropy and equilibrium free energy. In contrast, Our result involve the von Neumann entropy of the non-equilibrium state, and its corresponding non-equilibrium free energy \([23, 36]\).

In Refs. \([37, 38]\) appealing treatments of initial correlations were presented in terms of changes in mutual information and conditional entropy. Such quantities cannot be expressed as expectation values (observables), and their evaluation requires costly, or even impractical, system-environment tomography. In contrast, the CCI the initial correlation manifests only in terms measurable expectation values. Furthermore, Ref. \([37]\) assumes large environment, the availability of an external ancilla, and the feasibility of global operations on many copies of the setup. None of these assumptions are needed for the CCI. Finally, \([37]\) requires locally thermal states and therefore cannot handle the important initial states such
as the coupled thermal studied above \cite{27}. In Ref. \cite{39} an interesting exchange fluctuation theorem is suggested. However, this approach is valid only for systems that are initially in local equilibrium. Moreover, it has no entropy term as in the CI and the CCI. Thus, while \cite{37,38,39} constitute important contributions to the field, the findings in these studies do not overlap with the results presented in this section. In particular, in Sec. III we derive additional inequalities that were not obtained in Refs. \cite{37,38,39}.

Equation (28) was derived a setup prepared in a coupled thermal state \cite{27}. Its form seems to be rather different from the more general CCI \cite{24}. However, in appendix II we show that the same form also exists for a general initial state. In Appendix III we study in more detail two physically interesting system-environment interactions. The first is an energy conserving swap-like interaction, and the second is a simple dephasing interaction.

III. ADDITIONAL PASSIVITY INEQUALITIES AND THEIR APPLICATION

A. Using passivity to generate new thermodynamic inequalities

In Sec. IIIB it was shown that if an operator $A$ is passive w.r.t $\rho_0$, then $g(A)$ is also a passive operator w.r.t. $\rho_0$ where $g(x)$ is a monotonically increasing function in the domain covering the eigenvalues of $A$. As shown before the operator $B_{\text{tot}} = -\ln \rho_0$ is passive w.r.t. to $\rho_{\text{tot}}^0$ for any thermodynamic protocol. Its eigenvalues are non-negative. The function $g(x) = x^\alpha$ is an increasing function for $x \geq 0$ and $\alpha > 0$. As a result, we get a new family of global passivity inequalities

$$\Delta \langle B^{\alpha} \rangle \geq 0 \tag{30}$$

for any $\alpha > 0$ and for any thermodynamic protocol \cite{30}. For brevity in Sec. IIIB 'tot' is omitted and $B$ will always refer to the whole setup. The $\alpha = 1$ case was shown earlier to coincide with the CI in the case of initially uncoupled microbaths that interact with each other. Below we demonstrate using three examples that the inequalities \cite{30} have different physical content for different values of $\alpha$. This means that inequalities with $\alpha \neq 1$ carry information that is absent in the CI. We also note that different $\alpha$ inequalities obey a hierarchical structure as shown in Appendix IV.

B. Heat leaks detection

Let us assume that we are given a quantum chip (e.g. superconducting circuit with several qubits). The unitary operation that the chip is supposed to carry out is unknown to us, but we do have information on the number of qubits, qudits and so on, that constitute the input and output of the device. The thermodynamic challenge we face is to verify if this chip is isolated from the surroundings (for all practical purpose), or perhaps it interacts with some unaccounted for (hidden) heat bath, e.g., via spontaneous emission or thermalization to the substrate temperature. Note that the unitary implemented by the chip is in general not energy-conserving (involves work). Hence, energy conservation cannot be used to detect the heat leak to the hidden environment.

One possible approach is to perform state tomography of the final state of the setup and check if the eigenvalues of the density matrix have been modified by an external agent. However, tomography of several qubits is very hard to perform and impractical for dozens of qubits. This method of detecting heat leaks is therefore very costly.

Another possibility is to use the second law. We prepare the input state in a product of thermal states $\rho_0^{\text{tot}} = e^{-\sum \beta_i H_i} / Z$. According to the CI \cite{2} the final density matrix satisfies $\sum_i \beta_i \text{tr}[\rho_f^{x} H_i] \geq \sum_i \beta_i \text{tr}[\rho_0^{\text{tot}} H_i]$. Indeed, if this inequality does not hold, one can deduce that there is a heat leak in progress. Crucially, if the CI is not violated, no conclusion can be made, as it possible that the heat leak is too small to be detected by the CI.

The global passivity inequalities \cite{30} suggest a third possibility. A heat leak from the setup (chip) to some unaccounted environment cannot be described as a mixture of unitary on the setup only. Thus, in the presence of a heat leak from the chip, inequalities \cite{30} may be violated and indicate the presence of a heat leak.

As an example, we study a three-qubit circuit with CNOT interaction Hamiltonian between qubits 1 and 2, and qubits 2 and 3 (Fig. 4a). The CNOT interaction strength is $\epsilon = 1$ so the CNOT operation is implemented in a time $\hbar/\epsilon$. The two CNOT interactions operate simultaneously. In addition, there is a heat leak to a zero temperature bath (e.g. spontaneous emission) at a rate $\gamma = \epsilon/1000$. That is, a thousand CNOT cycles pass by before the decay becomes dominant. Nevertheless, our goal is to detect the heat leak as soon as possible since the chip typically operates only for a very short time with respect to $1/\gamma$.

The initial density matrix is $\rho_0^{\text{tot}} = e^{-\sum \beta_i \sigma_i^{(i)}} / Z$ with $\beta_1 = 1, \beta_2 = 0.5, \beta_3 = 0.1$. Fig. 4b shows that for the depicted time the effect of the decay on the polarization of the qubits is not visible. In Fig. 4a, we plot the values of $\Delta \langle B^{\alpha} \rangle$ as function of time for various $\alpha$ values. When the curves take negative values the heat leak is detected. The plot shows that larger $\alpha$ values can detect the heat leak much sooner compared to the $\alpha = 1$ (which in this case equivalent to the CI). It is important to emphasize that to evaluate $\Delta \langle B^{\alpha} \rangle$ only local energy measurements $\{E_1, E_2, E_3\}$ are needed in each realization (in each run of the experiment). $\langle B^{\alpha} \rangle$ is obtained by the mean value of $(\beta_1 E_1 + \beta_2 E_2 + \beta_3 E_3)^\alpha$ in many runs. This is a much less demanding task compared to a three-qubit tomography that involves many non local measurements.

These results show that different values of $\alpha$ contain
Hamiltonian are conserved (i.e., all energy moments are conserved). energy distributions of both the system and environment. Let us consider the case where additional inequalities (30), let us consider the case where the α = 1 curve that corresponds to the CI is always positive for the depicted time, it cannot be used to detect the heat leak. On the other hand the α = 5 and α = 6 global passivity inequalities are violated in less the 3/1000 of the decay time (which is 1/γ = 1000).

different physical information. Moreover, it raises the interesting question of the existence of sufficient conditions for guaranteed detection of any heat leak.

C. Bounds on system-environment correlation in a dephasing process

As an additional example for the usefulness of the additional inequalities [30], let us consider the case where a system is coupled to the environment via a dephasing interaction. A dephasing interaction \( H_I \) satisfies \( [H_I, H_{sys}] = 0 \) and as a result it cannot affect the energy populations of the system. We also assume that the interaction does not change the energy populations of the environment \( [H_I, H_{env}] = 0 \). In summary, the reduced energy distributions of both the system and environment are conserved (i.e., all energy moments are conserved).

In our example, the system is a single spin with a Hamiltonian \( H_s = \sigma_z \). This spin is prepared with some initial coherence in the \( x \) direction so that \( \rho_0^{sys} = e^{-\beta_s \sigma_z}/Z_{sys} \). As an environment we take a three-spin microbath at inverse temperature \( \beta \) (see inset in Fig. 5) and a Hamiltonian \( H_{env} = \sum_{i=1}^{3} \sigma_z^{(i)} \). The system and the microbath are initially uncorrelated. The total initial density matrix is

\[
\rho_0^{tot} = e^{-\beta H_{env} \otimes I_s - \beta_s H_{sys} \otimes \sigma_z}/Z,
\]

where \( I_{env}, I_s \) are identity operators in the Hilbert space of the microbath and the system, and \( Z \) normalizes the density matrix.

For convenience we define a shifted version of \( \hat{\beta} \)

\[
\hat{\beta} = \beta \hat{H}_{env} + \beta_s \hat{\sigma}_z, \tag{32}
\]

\[
\hat{H}_{env} = H_{env} \otimes I_s - E_{env,0} I, \tag{33}
\]

\[
\hat{\sigma}_z = I_{env} \otimes \sigma_z + 1/2I, \tag{34}
\]

where \( I = I_{env} \otimes I_s \) is the identity operator in the joint system-microbath space, and \( E_{env,0} \) is the ground state energy of the environment. Now \( \hat{H}_{env}, \hat{\sigma}_z \) and \( \hat{\beta} \) are all positive operators, and in addition it holds that \( \hat{\sigma}_z^2 = \hat{\sigma}_z \) which will be useful later on. This shift is needed to ensure that powers of \( \hat{\beta} \) will remain passive w.r.t. to \( \rho_0^{tot} \). For example, if the operator is shifted so that it contains both positive and negative eigenvalues, than squaring it will change the eigenvalues order and destroy passivity w.r.t. \( \rho_0^{tot} \). Alternatively stated \( \eta = \eta^2 \) is increasing only for \( \eta > 0 \) so \( \hat{\beta} \) must be non-negative for even orders of \( \eta \) to be passive.

Next we wish to find a bound on the covariance between the energy of the microbath and the \( \sigma_x \) values of the system at time \( t \), i.e., \( \text{cov}(H_{env}, \sigma_x)_t = \langle \hat{H}_{env} \sigma_x \rangle_t - \langle H_{env} \rangle \langle \sigma_x \rangle_t \). Since \( \langle H_{env} \rangle = \text{const} \) and \( \langle \sigma_x \rangle \) is easy to measure, the non trivial term is \( \langle H_{env} \sigma_x \rangle_t \). This term can be bounded using (30). After some algebra the \( \alpha \) = 2 inequality \( 2\beta_x \Delta \langle \hat{H}_{env} \hat{\sigma}_x \rangle \geq 2 \beta_x^2 \Delta \langle \sigma_x^2 \rangle \geq 0 \) leads to

\[
2 \beta_x \Delta \langle \hat{H}_{env} \hat{\sigma}_x \rangle \geq 2 \beta_x^2 \Delta \langle \sigma_x^2 \rangle = 2 \beta_x^2 \Delta \langle \hat{\sigma}_x \rangle. \tag{35}
\]

Subtracting \( \langle H_{env} \rangle \langle \sigma_x \rangle_t - \langle H_{env} \rangle \langle \sigma_x \rangle_0 \) we get

\[
\text{cov}(H_{env}, \sigma_x)_t \geq \left( \frac{\beta_x}{\beta} - \langle H_{env} \rangle \right) \Delta \langle \hat{\sigma}_x \rangle. \tag{36}
\]

We now turn to consider Eq. (30) with \( \alpha = 3 \). Some straightforward algebraic manipulations result in

\[
\text{cov}(P(\hat{H}_{env}^2), \sigma_x)_t \geq c_0 \Delta \langle \sigma_x \rangle, \tag{37}
\]

where

\[
P(\hat{H}_{env}^2) = (\beta \hat{H}_{env})^2 + \beta_s^2 (\beta \hat{H}_{env}), \tag{38}
\]

and \( c_0 = \left[ \frac{1}{2} \beta_x^2 - \langle \beta^2 \hat{H}_{env}^2 \rangle + \beta_s^2 (\beta \hat{H}_{env}) \right] \). Due to the dephasing interaction \( c_0 \) is fixed in time and process-independent.

Equations (36) and (37) bound the buildup of system-environment covariance. To test these thermodynamic bounds numerically we choose the interaction Hamiltonian \( H_I = \sum_{i=1}^{3} \xi_i \sigma_z^{(i)} \otimes \sigma_z^{sys} \) where \( \xi_1 = 0.7, \xi_2 = 0.5, \xi_3 = 0.3 \) that mimics a coupling that depends on the proximity of each microbath spin to the system. The blue curve in Fig. 5 shows the exact evolution of the correlation function \( \text{cov}(H_{env}, \sigma_x)_t = \text{cov}(H_{env}, \sigma_x)_0 / \sqrt{\text{Var}(H_{env}) \text{Var}(\sigma_x)} \). The red-shaded areas show the lower bound (36) obtained from the \( \alpha = 2 \) global passivity inequality. Figure 5, plots the correlation function \( P(\hat{H}_{env}^2), \sigma_x)_t = \text{cov}(P(\hat{H}_{env}^2), \sigma_x)_0 / \sqrt{\text{Var}(P(\hat{H}_{env}^2)) \text{Var}(\sigma_x)} \) (blue curve) and the lower bound (37) obtained from the \( \alpha = 3 \) global passivity inequality.

Using the \( \alpha \) global passivity inequalities (30) and (11), it is also possible to get other types of bounds. In the
A feedback is an operation applied to the system of interest, where the type of operation to be applied depends on the present state of the system. That is, the system is first measured and then different operations are executed depending on the measurement result. It is well known that feedback can completely change the thermodynamics of a process, and has to be properly accounted for. The most well-known example is Maxwell’s celebrated demon. In this thought experiment feedback is used to separate cold molecules from hot molecules, and thereby “violate” the second law of thermodynamics. A more modern viewpoint suggests the second law holds if the information gained by the measurement is taken into account, or if the demon and the system are treated jointly as one big setup. The thermodynamics of information has become an active research field with many theoretical advances. Several experimental realizations have also been reported.

In this section, we study the operation of a “lazy Maxwell’s demon”. As in Maxwell’s original thought experiment the demon attempts to create an “anomalous heat flow” where heat flows from the cold environment to the hot environment. Since the second law forbids such a heat flow in the absence of a feedback or external work, the presence of the demon can be detected if the CCI does not hold. To challenge the limits of thermodynamics we assume that our demon is lazy. Even when the conditions are such that the demon should take action (i.e. shut the trap door) it may doze off and do nothing. Specifically it will act a fraction $\chi$ of the time it should. When $\chi$ is sufficiently small ($\chi \leq \chi_{\text{crit}}$) no anomalous heat will be observed. Thus, the action of the demon will not violate the CCI, and the CCI cannot be used to detect the demon.

Similarly to the discussion in Sec. when the CCI holds we cannot exclude the presence of feedback. In particular, there are two cases where this strategy can fail: (1) the feedback is very weak with respect to the flows generated by the thermodynamic protocol. (2) The elements (e.g. microbath) are initially correlated so the CCI fails even without feedback. In this latter case, we can check for violation of the CCI. Yet, in this case as well, the feedback may be too weak to violate the CCI. Therefore, we focus here on the weak feedback scenario (small $\chi$).

The question we pose is: can thermodynamics be used to detect lazy demons that the CCI cannot detect ($\chi < \chi_{\text{crit}}$)? Below we present an example that demonstrates that the global passivity inequalities can do the job.

In quantum mechanics, feedback can be described in the following way. The demon measures an observable with outcome $k$. Depending on the result $k$ the experimentalist applies different unitaries $V_k$. The final density matrix with feedback is given by

$$
\rho_f^\text{tot} = \sum_{k'} V_{k'} \Pi_k \left( \sum_k p_k U_k \rho_0 U_k^\dagger \Pi_k \right) V_{k'}^\dagger
$$

where the expression in the square bracket is $\rho_f^\text{tot}$ just before the feedback. While both Eq. (6) and Eq. (39) are Kraus maps, Eq. (39) is not a mixture of unitaries due to the presence of the measurement projectors. Hence, the inequalities are guaranteed to hold for while for (39) they may be violated ($\Delta \langle B^\alpha \rangle < 0$). This can be used to detect whether a feedback has been applied to the system.

Obviously, if for a specific $\alpha$ the inequality $\Delta \langle B^\alpha \rangle \geq 0$ holds, the presence of a demon cannot be excluded.
and other $\alpha$ values should be checked. The interesting question about the existence of a sufficient set of tests to detect any feedback is outside the scope of the present paper and will be explored elsewhere. Our more modest goal here is simply to demonstrate that in some cases the global passivity inequalities can detect weak feedback that the CI cannot detect.

To illustrate how the global passivity inequalities can assist in feedback detection, we study a simple setup of two microbaths composed of two spins each (Fig. 6a). The cold (hot) microbath is initially prepared in temperature $T_c = 1.5$ ($T_h = 2.5$). The Hamiltonian of the setup before the interaction is $H_0 = \sum_{i=1}^4 \sigma_z^{(i)}$. The initial state of the setup is $\rho_0 = \exp[-\beta_c(\sigma_z^{(1)} + \sigma_z^{(2)}) - \beta_h(\sigma_z^{(3)} + \sigma_z^{(4)})]/Z$. At $t = 0$ an “all to all” interaction is turned on: $H_I = \sum_{i>j}^4 \sigma_z^{(i)}\sigma_z^{(j)} + \sigma_z^{(i)}\sigma_z^{(j)}$. Such “all to all” coupling can be realized in ion traps or in superconducting qubits. The system evolves until $t = 1$ under the Hamiltonian $H = H_0 + H_I$. After the evolution, the demon is awake with probability $\chi$ and then it measures the setup. If the demon finds the setup to be in the state $|\uparrow\downarrow\downarrow\uparrow\rangle$ it changes it to $|\downarrow\downarrow\uparrow\downarrow\rangle$ (where $\uparrow$ and $\downarrow$ stand for spin up or spin down states). In all other cases, the demon does nothing. This operation is energy conserving and transfers energy (heat) from the cold microbath to the hot microbath. Thus, no work is involved in applying this feedback. The process is shown in Fig. 6b. Numerically, we apply the feedback and check if it is detectable. For $\chi = 0$ (the demon never does anything) heat flows to the cold microbath, and the dynamics is consistent with the CI. Thus for small values of $\chi$ this very subtle form of feedback may not be detectable by the CI.

Since our setup includes two microbaths and no system, the inequality \(30\) with $\alpha = 1$ is identical to the CI \(14\), $\beta_c q_c + \beta_h q_h \geq 0$. We find that for $\chi$ values exceeding $\chi_{\text{crit}} \approx 0.56$ heat flows from the cold microbath to the hot microbath and the demon is detectable by the CI \(14\). For other $\alpha$ values we denote by $\chi^*(\alpha) = \min_\chi (\Delta (B^{(\alpha)}) < 0$) the smallest feedback strength that leads to violation of $\Delta (B^{(\alpha)}) \geq 0$. The blue curve in Fig. 6h shows $\chi^*(\alpha)$. Interestingly, this curve is not necessarily monotonically decreasing with $\alpha$. For this feedback operation, we find that among the $\alpha$ inequalities \(30\) there is an optimal value $\alpha_{\text{opt}} \approx 2.6$ where the largest detection range is observed (right green arrow). In this example, the best detection takes place for a non integer value of $\alpha$. This gives a justification for studying also fractional values of $\alpha$.

Figure 6 shows that the global passivity inequalities \(30\) successfully detect “lazy demons” that the CI cannot detect. As in Sec. IV, these results demonstrate that different values of $\alpha$ contain different physical information.

**IV. CONCLUSION**

The second law of thermodynamics is one the pillars of theoretical physics with countless applications in engineering and science. It was originally formulated for macroscopic systems and reservoirs where one could assume weak coupling, extensivity, and lack of recurrences. Under some restrictions, the second law can also be applied to microscopic systems and microscopic environments. However, these restrictions exclude important microscopic setups. In other microscopic scenarios (e.g., dephasing), the second law is valid but provides trivial information that is of little use.

In this paper, we have introduced the notion of global passivity. We have shown that under the standard thermodynamic assumptions global passivity (complemented by passivity-divergence relation) recovers the Clausius inequality formulation of the second law. We then show that global passivity leads to a modified Clausius inequality that remains valid even when the system and environment are initially strongly correlated. This extension is important since for small systems the interaction between system and environment and the resulting initial correlations are in general non-negligible and the standard second law (in particular the Clausius inequality form) cannot be used.

Our second main finding is a continuous family of global passivity inequalities that accompany the second law. We have demonstrated how they can be used to detect heat leaks and feedback (demons) in cases where...
the second law fails to do so. In addition, the same inequalities were used to put upper and lower bounds on the buildup of system-environment covariance in a dephasing scenario. Such predictions are presently outside the scope of other modern thermodynamic frameworks (e.g., stochastic thermodynamics, and thermodynamic resource theory).

Beyond the two main findings of this paper, the global passivity formalism presents a set of tools that impose restrictions on observables in thermodynamic processes in quantum systems. As an example, in a different publication, we will study the intimate relation between passivity-divergence relation and quantum coherence measures. Further research is needed in order to identify which inequalities are the most useful for a given setup.

The present predictions of global passivity are relevant to present day experimental setups such as ion traps, superconducting circuits, optical lattices, and NMR.

APPENDIX I - THE ALL OBSERVABLE ANALOG OF THE CLAUSIUS INEQUALITY

Let us start with the standard initial condition of thermodynamic setups (assumption 1&2 in Sec. II A)

\[ \rho_0^{\text{tot}} = \rho_0^{\text{sys}} \otimes \rho^{- \sum \beta_k H_k} / Z, \]  

where \( Z \) is a normalization factor, \( H_k \) is the Hamiltonian of microbath \( k \), and \( \beta_k \) is its inverse temperature at time zero. Substituting (40) in the global passivity inequality (17) gives

\[ \Delta \langle B^{\text{sys}} \rangle + \sum_k \beta_k q_k \geq 0, \]  

where

\[ B^{\text{sys}} = - \ln \rho_0^{\text{sys}}. \]  

Equation (41) is the observable-only analog of the CI. It contains only linear terms in the final density matrix. The CI and Eq. (41) both reduce to \( \sum_k \beta_k q_k \geq 0 \) in two important cases: 1) when there is no mediating system (e.g., in absorption refrigerators with a tricycle interaction [12, 17]). 2) In (quasi) stationary periodic operation of a heat machine interacting with a large bath, where \( \Delta \langle B^{\text{sys}} \rangle \) is negligible with respect to the accumulated heat exchanges.

Despite the similarities, Eq. (41) and the CI differ on a fundamental level. The Eq. (41) contains only changes in expectation values of operators. Alternatively stated, it is linear in the final density matrix \( \rho_f^{\text{tot}} \). It is nonlinear in \( \rho_0^{\text{tot}} \) but this is due to the fact that the observable \( B \) is constructed from \( \rho_0^{\text{tot}} \). In contrast, the term \( \Delta S^{\text{sys}} \) in the CI does not have an expectation value structure and it is a non-linear function of \( \rho_f^{\text{tot}} \).

Even though the CI and Eq. (41) involve different quantities, they can be quantitatively compared, as both provide a prediction on the quantity \( \sum \beta_k q_k \). Using the identity (18) for the system density matrix, Eq. (41) can be recast as

\[ \Delta S^{\text{sys}} + \sum_k \beta_k q_k \geq - D(\rho_f^{\text{sys}} | \rho_0^{\text{sys}}). \]  

Since the r.h.s. of is negative it becomes evident that the CI (2) is tighter inequality compared to Eq. (41). On the other hand, it is important to emphasize that Eq. (41) takes less resources to evaluate in comparison to the CI.

To evaluate the \( \Delta S^{\text{sys}} \) term in the CI a full system tomography is needed. In contrast, in Eq. (41) we measure one observable of the system \( \rho_f^{\text{sys}} \). Only the diagonal elements of the density matrix in the basis of \( B^{\text{sys}} \) are needed. Moreover, we do not need to know explicitly the diagonal elements of \( \rho_0^{\text{sys}} \); \( \langle B^{\text{sys}} \rangle \) can be directly measured without evaluating the probability distribution in the \( B^{\text{sys}} \) basis. Thus, in terms of utility for experiments, Eq. (41) is easier to check compared to the CI. That said, the CI offers some insight on the relationship between information (entropy) and energy that is absent in Eq. (41).

APPENDIX II - OBSERVABLES INSPIRED BY PASSIVITY

The CCI (24) is given in terms of expectation values that are determined by the initial density matrix. When the initial density matrix is related to some observable, the CCI expectation values will also be related to this observable. For example, in thermodynamics, the microbaths are determined by their initial temperature and their Hamiltonian so \( B^{\text{bath}} \) or \( B^{\text{tot}} - B^{\text{sys}} \) can be related to the Hamiltonian. In this appendix, we address the general case where there is no prior knowledge about the operator associated with the setup preparation. We limit our discussion to two initially correlated parties. The extension to more parties is trivial.

\[ B^{\text{tot}} = - \ln \rho_0^{\text{tot}} \]  

is a positive Hermitian operator, and it can be decomposed in the following way:
\[ B^{\text{tot}} = \sum_{i=1}^{L_A} r_{A,i} Z_i \otimes \frac{I_{N_B} \times N_B}{N_B} + \sum_{j=1}^{L_A-1} \sum_{i=1}^{L_B-1} t_{ij} Z_i \otimes Z_j, \]

where \( L_A(B) = N_A(B) - N_A(B), \) and \( \{ Z_{i(j)} \}_{1}^{L_A(B)-1} \) are traceless orthonormal basis operators for \( N_A(B) \times N_A(B) \) Hermitian traceless matrices. \( Z_{L_A(B)} \) are the identity operators in each party. Finally \( r_A \) and \( r_B \) determine the reduced density matrices:

\[ \text{tr}_B B^{\text{tot}} = \sum_{i=1}^{L_A} r_{A,i} Z_i = B_A. \]

This suggest that \( B^{\text{tot}} = B_A + B_B + B_{\text{int}} \) where \( B_{\text{int}} \) has an interaction Hamiltonian form \( B_{\text{int}} = \sum_{ij} t_{ij} Z_i \otimes Z_j. \) Now let A be the system and B be the environment. We find that CCI has the form:

\[ \Delta S^\text{sys} + \Delta \langle B^{\text{bath}} \rangle + \Delta \langle B^{\text{int}} \rangle + \Delta \langle B^{\text{sys}} - B^{\text{sys}}_{\text{eff}} \rangle \geq 0 \]

where

\[ B^{\text{bath}} = \text{tr}_B \langle -\ln \rho^{\text{tot}} \rangle, \]
\[ B^{\text{sys}} = \text{tr}_B \langle -\ln \rho^{\text{tot}} \rangle, \]
\[ B^{\text{sys}}_{\text{eff}} = -\text{tr}_B \langle -\ln \rho^{\text{tot}} \rangle. \]

Thus the dressing term originate from the non commutativity of the partial trace operation and the \(-\ln\) operation. The two commute when \( \rho^{\text{tot}}_0 \) is in a system-environment product state.

**APPENDIX III - THE CCI FOR TWO SIMPLE INTERACTIONS IN A COUPLED THERMAL STATE**

In this appendix, we evaluate the magnitude of the system dressing term in the CCI with an initially coupled thermal state (see Sec. [14]). One particularly interesting cases. First, we make the simplifying assumption that \( H_{1,0} \) conserves the sum of bare energy of the system and the microbath

\[ [H_{1,0}, H_s + H_{\text{mb}}] = 0. \]

Using this condition we find

\[ \text{tr}_B e^{-\beta(H_s + H_{1,0} + H_b)} = e^{-\beta H_s} \text{tr}_B [e^{-\beta H_b} e^{-\beta H_{1,0}}] = e^{-\beta H_s} \sum_{E_b} e^{-\beta E_b} \langle E_b | e^{-\beta H_{1,0}} | E_b \rangle. \]

where in the last stage we have used the microbath energy eigenstates to do the partial trace.

We consider two typical forms of \( H_{1,0}: \) (1) \( \epsilon \mathcal{H}_s \otimes \mathcal{H}_b \) where \( [\mathcal{H}_b, H_s] = [\mathcal{H}_s, H_s] = 0 \) which often arises in dephasing environments, e.g. \( \sigma_z \otimes \sigma_z. \) (2) a swap-like interaction between the system and the microbath \( a_b^{\dagger} \otimes a_s + h.c. \) where \( a \) is some transition operator of the form \( |m \rangle \langle n| \).

For case (1), simple dephasing, we find

\[ \text{tr}_B e^{-\beta (H_s + H_{1,0} + H_b)} = e^{-\beta H_s} \sum_{n=0} \frac{(-\beta \epsilon)^n}{n!} \langle H_b^n \rangle \otimes Z_{60}, \]

and [52] we get

\[ \beta \Delta (H_{1,0}^{\text{sys}} - H_s) = \ln f(-\beta \epsilon H_s) = (\beta \epsilon) \tilde{H}_s \langle H_b \rangle_0 Z_{60} + O[(\beta \epsilon)^2] \]

Since \( \tilde{H}_s \) commute with \( H_s \) we conclude that \( \ln f(-\beta \epsilon H_s) \) is a “dressing effect” of the microbath on the system (this term has the same eigenstates as \( H_s \)). In the CCI [24], the system appears primarily in \( \Delta S^\text{sys} \) as in the CI. However, in the CCI the dephasing dressing effect contributed a new expectation value term (in contrast to information term) of the system [53].

For case (2), the creation-annihilation swap-like interaction we find,

\[ \text{tr}_B e^{-\beta (H_s + H_{1,0} + H_b)} = e^{-\beta H_s} \sum_{E_b} e^{-\beta E_b} \langle E_b | e^{-\beta H_{1,0}} | E_b \rangle \]

\[ = e^{-\beta H_s} \sum_{E_b} e^{-\beta E_b} \langle E_b | \cosh(\beta H_{1,0}) | E_b \rangle. \]

The cosh appears since all the odd powers of \( e^{-\beta H_{1,0}} \) are eliminated by the partial trace. From this we conclude that contribution of the swap term is \( O[(\beta \epsilon)^2] \). Therefore, if there is a weak swap term at time zero, it will manifest in the first order in the \( \beta \Delta (H_{1,0}) \) term of the CCI, and only in second order in the system dressing term of the CCI.

**APPENDIX IV - B**$^*$**HIERARCHY RELATIONS**

In this Appendix we point out that there is a hierarchy relation between inequalities [30] with different values
of $\alpha$. The derivation is based on the fact that for any $q > p > 0$ the function $h(x) = \frac{x^q}{p} - \frac{x^p}{q}$ is monotonically increasing for $x \in [0, 1]$. To apply this to the operator $\mathcal{B} = -\ln \rho_0^\text{tot}$ we define the operator $\tilde{\mathcal{B}} = \mathcal{B}/\|\mathcal{B}\|_\text{op}$ where $\|\mathcal{B}\|_\text{op}$ is the operator norm, which is equal to the largest eigenvalue of $\mathcal{B}$ (is Hermitian and bounded). Based on this construction $h(\tilde{\mathcal{B}})$ is passive w.r.t to $\rho_0^\text{tot}$ since we ensured that the spectrum of $\tilde{\mathcal{B}}$ is in $[0, 1]$ where $h(x)$ is an increasing function. Thus from passivity we get that $\Delta h(\tilde{\mathcal{B}}) \geq 0$ which means that

$$\frac{\Delta \langle B^p \rangle}{p \|B\|_{op}^p} \geq \frac{\Delta \langle B^q \rangle}{q \|B\|_{op}^q}, \forall p > q > 0.$$  \hspace{1cm} (55)

In particular for integer $p$ and $q$ we get

$$\frac{\Delta \langle B^p \rangle}{\|B\|_{op}^p} \geq \frac{1}{2} \frac{\Delta \langle B^2 \rangle}{\|B\|_{op}^2} \geq \frac{1}{3} \frac{\Delta \langle B^3 \rangle}{\|B\|_{op}^3} \geq \ldots \geq \frac{1}{n} \frac{\Delta \langle B^n \rangle}{\|B\|_{op}^n} \geq 0.$$  \hspace{1cm} (56)

These relations can be useful for bounded setups (e.g. collection of spin) as long as the operator $\mathcal{B}$ is bounded and not too large (e.g. when the setup include a small number of spins). For large $\|B\|_{op}$ the hierarchy relations reduce to \cite{30}.
