Bayesian state-space modeling for analyzing heterogeneous network effects of US monetary policy

NIKO HAUZENBERGER and MICHAEL PFARRHOFER*

University of Salzburg

Understanding disaggregate channels in the transmission of monetary policy to the real and financial sectors is of crucial importance for effectively implementing policy measures. We extend the empirical econometric literature on the role of production networks in the propagation of shocks along two dimensions. First, we set forth a Bayesian spatial panel state-space model that assumes time variation in the spatial dependence parameter, and apply the framework to a study of measuring network effects of US monetary policy on the industry level. Second, we account for cross-sectional heterogeneity and cluster impacts of monetary policy shocks to production industries via a sparse finite Gaussian mixture model. The results suggest substantial heterogeneities in the responses of industries to surprise monetary policy shocks. Moreover, we find that the role of network effects varies strongly over time. In particular, US recessions tend to coincide with periods where between 40 to 60 percent of the overall effects can be attributed to network effects; expansionary economic episodes show muted network effects with magnitudes of roughly 20 to 30 percent.

1. INTRODUCTION

A growing number of papers explores how shocks on the micro- and macro-level propagate through economic networks and how such shocks relate to aggregate fluctuations. Most articles provide substantial evidence for the importance of network effects (see, for instance, Gabaix, 2011; Acemoglu et al., 2012; Elliott et al., 2014; Acemoglu et al., 2015; Ozdagli and Weber, 2017). Recent empirical analyses, however, suffer from a set of limiting shortcomings: they mainly rely on constant parameter specifications and either focus on aggregate data or neglect heterogeneities among cross-sectional observations.

In this article, we address these issues and extend the literature on spatial panel data models (see, for instance, Elhorst, 2014; Aquaro et al., 2015; LeSage and Chih, 2016), linking them to the vast literature on Bayesian state-space modeling (see Kim and Nelson, 1999). As a topical application, we focus on the transmission of monetary policy shocks through the US production network. Our approach is closely related to Ozdagli and Weber (2017), who generalize the setup proposed in Bernanke and Kuttner (2005) and Gürkaynak et al. (2005) for analyzing the impact of changes in monetary policy on equity prices. While Bernanke and Kuttner (2005) and Gürkaynak et al. (2005) focus mostly on aggregate data like the S&;P500 index, Ozdagli and Weber (2017) find substantial evidence for higher-order effects of monetary policy on stock market returns using disaggregate data on the industry-level, and attribute between 60 to 80 percent of the total effects to spillovers between industries.

In the empirical application, however, Ozdagli and Weber (2017) neglect industry specific idiosyncrasies and disregard time-variation in the strength of network dependencies. This is problematic for two reasons. First, pooling information across industries may conceal important underlying structural relationships, and potentially distorts the estimated importance of some industries in the disaggregate transmission of monetary policy shocks compared to others (see also Bernanke and Kuttner, 2005). Second, structural breaks in macroeconomic and financial series are increasingly drawing interest in the related literature (see, for instance, Cogley and Sargent, 2005; Primiceri, 2005; Sims and Zha, 2006). Time-varying parameter models are a popular tool for alleviating concerns of misspecification arising from nonlinear dynamics in small-scale models (Feldkircher et al., 2017).

To address these empirical shortcomings and circumvent concerns of biases, we develop a Bayesian state-space model for analyzing network effects of US monetary policy, allowing for heterogeneity both over time and the cross-section. Our contributions are thus both of methodological and empirical nature. First, we assume the spatial dependence parameter to vary over time via imposing a random walk state-equation, and provide Bayesian prior and posterior distributions alongside a sampling algorithm for inference. Second, we address how to efficiently exploit cross-sectional information for obtaining precise inference, but allow for heterogeneous

1These articles are among a larger body of diverse literature focusing on measuring monetary non-neturality using high-frequency market surprises around central bank policy announcements (see Kuttner, 2001; Cochrane and Piazzesi, 2002; Gürkaynak et al., 2005; Gertler and Karadi, 2015; Nakamura and Steinsson, 2018; Altavilla et al., 2019; Jarociński and Karadi, 2019).
effects across units in a stochastic fashion. Most of the established spatial methods for panel data analysis rely on deterministic data transformations such as fixed effects. By contrast, we take a fully Bayesian stance by imposing a hierarchical shrinkage prior on the regression coefficients and the residual variances. In particular, we base our prior setup on sparse finite Gaussian mixtures (see Malsiner-Walli et al., 2016), providing a link to the literature on random coefficient and heterogeneity models (Verbeke and Lesaffre, 1996; Allenby et al., 1998; Frühwirth-Schnatter et al., 2004).

From an empirical perspective, two main findings are worth noting. First, there is substantial evidence pointing towards the necessity of addressing industry specific reactions to monetary surprises. Estimated effects are much smaller when disregarding the notion that some industries are more sensitive to Fed policy changes than others, up to a magnitude of roughly one percentage point. In particular, we find that the average stock market response across industries to a one percentage point surprise increase in federal funds futures translates to a median response across all industries of approximately 1.9 percentage points, with industry-specific estimates up to five percentage points. Second, we find substantial evidence for time-variation in the strength of network dependency structures. In particular, US recessions tend to coincide with periods where between 40 to 60 percent of the overall effects can be attributed to network effects; expansionary economic episodes show muted network effects with magnitudes of around 20 to 30 percent.

The remainder of the paper is structured as follows. In Section 2, we set forth the spatial panel model. Section 3 discusses the Bayesian prior setup and provides a Gibbs sampling algorithm for inference. We apply the model in a study of the network effects of US monetary policy in Section 5. Section 6 concludes.

2. A TIME-VARYING SPATIAL DEPENDENCE PANEL MODEL

The baseline model is in the spirit of spatial panel specifications and can be written for observation i = 1, . . . , N as

\[ y_{it} = \rho_t \sum_{j=1}^{N} w_{ij} y_{jt} + \alpha_i + \mathbf{x}_{it}' \beta_i + \epsilon_{it}, \quad \epsilon_{it} \sim \mathcal{N}(0, \sigma_i^2), \]

where \( y_{it} \) is the response variable at time \( t = 1, \ldots, T \). We include \( K \) exogenous covariates in the \( K \times 1 \)-vector \( \mathbf{x}_{it} \) with associated observation specific parameter vector \( \beta_i \) of size \( K \times 1 \) and a Gaussian error term with zero mean and variance \( \sigma_i^2 \).

Information on the cross-sectional dependency structure is incorporated using weighted averages of the “foreign” quantities \( y_{jt} \) (\( j = 1, \ldots, N \)) with exogenous weights \( w_{ij} \) denoting the elements of an \( N \times N \) weighting matrix \( \mathbf{W} \) subject to the typical restrictions \( w_{ii} = 0, w_{ij} \geq 0 \) and \( \sum_{j=1}^{N} w_{ij} = 1 \) that guarantee the stability of the model. The first novelty proposed in this

---

2 For a recent paper addressing heterogeneity over the cross-sectional dimension in the spatial econometric context, see Cornwall and Parent (2017). For a textbook introduction on mixture models for panel data, see Frühwirth-Schnatter (2006).

3 The proposed framework for the static version of the panel model adopted for the empirical application in this paper can easily be extended to more flexible specifications, including dynamic models, and setups allowing for stochastic volatilities.
paper is that the scalar parameter $\rho_t$ features time-variation. The state equation for the spatial dependence parameter $\rho_t$ is a random walk process:

$$\rho_t = \rho_{t-1} + \varsigma \xi_t, \quad \xi_t \sim \mathcal{N}(0, 1). \quad (2)$$

Established econometric methods typically rely on constant spatial dependency structures. Note that $\varsigma = 0$ implies that the model collapses to a constant parameter model, and testing whether the data suggests time-varying spatial dependence is thus a variance selection problem, as discussed in the context of a standard time-varying parameter model by Frühwirth-Schnatter and Wagner (2010). We exploit this fact below by imposing a suitable shrinkage prior on these variances that pushes the model towards the constant parameter specification if suggested by likelihood information.

2.1. Interpreting the model coefficients

The approach to modeling spatial dependence pursued in this paper establishes a large system of simultaneous equations with specific parametric restrictions. Consequently, standard interpretations for linear regressions have to be adapted to account for the notion of cross-sectional dependencies. Here, we follow LeSage and Chih (2016) and derive the impact matrix for the $k$th coefficient for $k = 1, \ldots, K$ with respect to a change in the $k$th exogenous covariate $x_{kt} = (x_{1kt}, \ldots, x_{Nkt})'$ for all cross-sectional units as

$$\frac{\partial y_{t}}{\partial x_{kt}} = S_{kt} = (I_N - \rho_t W)^{-1} B_k.$$

Here, $B_k = \text{diag}(\beta_{1k}, \ldots, \beta_{Nk})$ with $\beta_{ik}$ referring to the $k$th coefficient of observation $i$. Following LeSage and Pace (2009), it is conventional to define $1/N \times \text{tr}(S_{kt})$ as the average direct effect, $1/N \times \iota_N' S_{kt} \iota_N$ as the average total effect, and the difference between the two as the average indirect, or network effect. Assuming time-varying spatial dependence yields an impact matrix $S_{kt}$ for $t = 1, \ldots, T$.

It is worth mentioning that the Bayesian approach we set forth allows for adequate quantification of uncertainty surrounding all model parameters and functions thereof. Besides full posterior distributions of the total, direct and indirect effects, we obtain confidence bounds for the overall strength of the network effects over time.

3. PRIOR SPECIFICATION

We estimate the proposed model using Bayesian methods. This involves selecting suitable prior distributions for all parameters and combining them with the likelihood of the data. We first discuss the prior setup for the time-varying spatial dependence parameter. Conditional on a draw of the full history of this parameter $\{\rho_t\}_{t=1}^T$, inference for the other model parameters is mostly standard, and we subsequently discuss the prior setup for the regressions coefficients and the error variances.
3.1. A spike-and-slab prior testing for time variation

For the spatial dependence parameter, we propose a prior setup that stochastically determines whether time-variation is required for adequately capturing observed dynamics, nesting conventional constant parameter specifications as a special case of our framework. We adapt a variant of the well known stochastic search variable selection prior of George and McCulloch (1993) in the context of the time-varying parameter model (for a related approach, see Frühwirth-Schnatter and Wagner, 2010).

We impose a mixture of two gamma priors allowing either for substantial mass close to zero, suppressing time variation, or loose enough to allow for time-varying spatial dependence. In particular, we specify a mixture of two Gaussians on the signed square root of the innovation variance in Eq. (2),

\[ \pm \varsigma \sim \delta \times \mathcal{N}(0, B_1) + (1 - \delta) \times \mathcal{N}(0, B_0), \]

with \( B_1 \gg B_0 \) and \( B_0 \) close to zero, which is equivalent to stating

\[ \varsigma^2 \sim \delta \times \mathcal{G} \left( \frac{1}{2}, \frac{1}{2B_1} \right) + (1 - \delta) \times \mathcal{G} \left( \frac{1}{2}, \frac{1}{2B_0} \right). \]

The latent binary indicator \( \delta \) dictates which one of the two components is active. Given \( \delta = 1 \), the prior on \( \varsigma^2 \) is rather loose based on larger values of \( B_1 \) and reflects time variation in the spatial dependence parameter by allowing for non-zero variances of the error term in the state equation. For \( \delta = 0 \), the second component with variance \( B_0 \) close to zero is active, pushing the signed square root of the innovation variance towards zero, effectively ruling out time variation. As a byproduct, this specification yields a posterior probability measure whether time variation for these coefficients is necessary to adequately reflect the data generating process. The binary indicators \( \delta \) are assigned a Bernoulli distribution \( \delta \sim \text{BER}(p) \) with prior inclusion probability \( p = 0.5 \). This establishes a prior that assumes constant and time-varying spatial dependence to be equally likely.

3.2. Sparse finite mixtures to pool coefficients

There are multiple possibilities to estimate observation specific parameters \( \theta_i = \{\alpha_i, \beta_i, \sigma_i\} \) for \( i = 1, \ldots, N \), with two extreme cases: either one decides to pool information over the cross-section, restricting \( \theta_i \) to be equal for all units, or one introduces truly observation specific parameters. The first restriction, especially in the empirical application of this paper, is likely to be overly restrictive and may mask important structural dynamics. The second variant, however, implies estimating a large number of parameters, and may thus result in imprecise estimates and overfitting issues.

In this paper, we allow for heterogeneous parameters per unit \( i \), but introduce a hierarchical prior that exploits cross-sectional information for more precise inference and pushes similar clusters of observations towards estimated cluster-specific common means. We follow Malsiner-Walli et al. (2016) and introduce a sparse finite mixture of Gaussians prior for the observation
specific regression coefficients $\beta_i$, resembling a random effects specification (Verbeke and Lesaffre, 1996; Allenby et al., 1998; Frühwirth-Schnatter et al., 2004). The prior is given by

$$f_{\mathcal{N}}(\beta_i|\omega_m, \{ \mu_m \}_{m=1}^M, V) = \sum_{m=1}^M \omega_m f_{\mathcal{N}}(\beta_i|\mu_m, V),$$

(3)

where $f_{\mathcal{N}}$ denotes the Gaussian probability density function, $\{ \omega_m \}_{m=1}^M$ are mixture weights and $\{ \mu_m \}_{m=1}^M$ refer to group-specific means for a pre-determined number of $M$ clusters. By introducing an auxiliary variable $\eta_i$, Eq. (3) can be rewritten as:

$$\beta_i|\eta_i = m, \mu_m, V \sim \mathcal{N}(\mu_m, V),$$

(4)

with $\eta_i = m$ denoting an integer indicating that $\beta_i$ belongs to the $m$th cluster. Consequently, $\Pr(\eta_i = m) = \omega_m$ refers to the assignment probability of $\beta_i$ to $m$. Moreover, $V = \text{diag}(v_1, \ldots, v_K)$ denotes a common $K$-dimensional diagonal prior covariance matrix. We select independent inverse gamma priors for the diagonal elements $v_k$ ($k = 1, \ldots, K$) of the prior covariance matrix, $v_k \sim \mathcal{G}^{-1}(d_0, d_1)$, with $d_0 = 3$ and $d_1 = 0.03$ set weakly informative.

We specify a shrinkage prior on the mixture component weights. A priori, $M$ is chosen to be large value, translating into an overfitting mixture specification. A natural choice for achieving shrinkage of the components, following Malsiner-Walli et al. (2016), is to assign a Dirichlet prior on $\omega = (\omega_1, \ldots, \omega_M)$ subject to the typical restrictions $\sum_{m=1}^M \omega_m = 1$ and $\omega_m \geq 0$ for $m = 1, \ldots, M$:

$$\omega|\kappa \sim D(\kappa, \ldots, \kappa).$$

Here, $\kappa$ is of crucial importance, since it determines how irrelevant clusters are treated; shrinking $\kappa$ empties clusters and thus ensures a parsimonious mixture representation with only a moderate number of groups. Shrinkage is achieved via a gamma distributed prior on $\kappa \sim \mathcal{G}(\vartheta, \vartheta M)$, with $\mathcal{G}$ denoting the gamma distribution with shape $\vartheta$ and scale $\vartheta M$. In the empirical application, we follow Malsiner-Walli et al. (2016) and define $\vartheta = 10$, introducing heavier shrinkage with increasing $M$.\footnote{Note that the expectation of $\kappa$ is given by $\mathbb{E}(\kappa) = 1/M$ and the variance is $\text{Var}(\kappa) = 1/(\vartheta M^2)$.}

To achieve further parsimony, we combine the shrinkage prior on the weights with shrinkage on the mixture-specific means (Yau and Holmes, 2011; Malsiner-Walli et al., 2016):

$$\mu_m \sim \mathcal{N}(\mu_0, V_0),$$

with $\mu_0$ referring to a common mean and $V_0 = LRL$ denoting the prior covariance matrix for the component means $\mu_m$. $L = \text{diag}(\sqrt{l_1}, \ldots, \sqrt{l_K})$ is a $K$-dimensional diagonal matrix, collecting the coefficient-specific shrinkage parameters $l_j$ for $j = 1, \ldots, K$ and $R = \text{diag}(R^2_1, \ldots, R^2_K)$ refers to a $K$-dimensional diagonal matrix with the $j$th element $R^2_j$ given by the range of $(\mu_{1j}, \ldots, \mu_{Mj})$. In what follows, we specify a normal gamma shrinkage prior (Griffin and Brown, 2010) on $\mu_m$.
assuming that \( l_j (j = 1, \ldots, K) \) is gamma distributed,

\[
l_j \sim \mathcal{G}(e_0, e_1).
\]

In the empirical application, we specify \( e_0 = e_1 = 0.1 \). To complete the set-up for the regression coefficients, we specify an improper Gaussian prior on the common mean \( \mu_0 \sim \mathcal{N}(0, Q) \), centered on zero and with precision \( Q^{-1} = 0_K \).

So far, we remained silent on how we specify the priors for the unit-specific error variances \( \sigma^2_i \). Here, we choose to cluster variances for the \( M \) groups and use a conjugate inverse gamma hierarchical prior (Frühwirth-Schnatter, 2006),

\[
\sigma^2_m \sim \mathcal{G}^{-1}(\xi, \Xi), \quad \Xi \sim \mathcal{G}^{-1}(\psi, \Psi).
\]

with hyperparameters specified as \( \xi = 2.5 + (T - 1)/2, \psi = 0.5 + (T - 1)/2 \) and \( \Psi = 100\psi/(\xi R_y^2) \). \( R_y \) denotes the range of the dependent variable. The hierarchical structure again implies that the group variances \( \sigma^2_m \) arise from a common distribution (Malsiner-Walli et al., 2016). The cluster specific variance \( \sigma^2_m \) is assigned to all observations \( i \) that are associated with the \( m \)th cluster.\(^6\)

4. POSTERIOR COMPUTATION

Combining the likelihood of the model with the proposed prior distributions yields a set of well-known conditional posterior distributions that can be used for setting up a Markov Chain Monte Carlo (MCMC) sampling algorithm. Most of the quantities involved are standard, and we discuss details on the posteriors for the mixture model set forth in Malsiner-Walli et al. (2016) alongside the sampling algorithm in Appendices A and B.

Producing draws for the full history of the time-varying spatial dependence parameter, however, is novel to the literature. In the following, we propose a sampling algorithm for the time-varying spatial dependence parameter. Due to the non-Gaussian setup, Kalman-filter based methods (Carter and Kohn, 1994; Frühwirth-Schnatter, 1994) are inapplicable. Simulation from the posterior distribution can be carried out using a Metropolis-Hastings algorithm. We denote the current state of the respective quantity by \( s_{-1} \) and \( s \) refers to a proposal from the candidate density. The procedure is similar to the algorithm proposed in the context of Bayesian stochastic volatility models in Jacquier et al. (2002). We rely on three proposal densities:

1. For all points in time other than the first and last observation, a draw \( \rho_t^{(s)} \) is generated from the proposal distribution given by \( \rho_t^{(s)} \sim \mathcal{N}(\mu_t, S_t) \), with \( \mu_t = (\rho_{t-1}^{(s-1)} + \rho_{t+1}^{(s-1)})/2 \) and \( S_t = \xi^2/2 \).

\(^5\) As suggested by Malsiner-Walli et al. (2016), \( e_0 < 1 \) is important to strongly push \( \mu_m \) towards a common mean to avoid overlapping component-specific densities. This specification contrasts to Yau and Holmes (2011), who choose a Lasso prior on \( l_j \) with \( e_0 = 1 \) (see also Park and Casella, 2008).

\(^6\) Identification issues in mixture models arising from label switching may be resolved by implementing a random permutation sampler and ex post clustering of the posterior draws, or using economic theory to impose restrictions on the component means or variances (see Frühwirth-Schnatter, 2001).
2. Since no initial value \( \rho_0 \) is available, we rely on Jacquier et al. (2002) who show that this quantity can be obtained by drawing from a Gaussian distribution \( \rho_0 \sim N(\mu_0, S_0) \). Under the prior \( \rho_0 \sim N(\mu_0, S_0^2) \), the corresponding moments are \( S_0 = \left( \gamma_0^2 + \gamma_0^2 \right) / (\gamma_0^2 + \gamma^2) \) and \( \mu_0 = \gamma_0^2 \left( \mu_0 / \gamma_0^2 + \mu_1^{(s-1)} / \gamma^2 \right) \). The proposal at \( t = 1 \) is then given by \( \rho_{1}^{(s)} \sim N(\mu_1, S_1) \) where \( \mu_1 = (\rho_0 + \mu_1^{(s-1)}) / 2 \) and \( S_1 = \gamma^2 / 2 \).

3. A similar problem arises for the final value at \( t = T \), due to no \( \rho_{T+1} \) being available. Jacquier et al. (2002) suggest drawing from the modified candidate density \( \rho_{T}^{(s)} \sim N(\mu_T, S_T) \) with \( \mu_T = \rho_{T-1}^{(s-1)} \) and \( S_T = \varsigma^2 \).

For each point in time, we generate a proposal for \( \rho_{t}^{(s)} \) that can be used to calculate the acceptance probability of the Metropolis-Hastings algorithm. To simplify notation, we define \( \tilde{y}_{it}(\rho_{t}^{(s)}) = \rho_{t}^{(s)} \sum_{j=1}^{N} \rho_{i,j} \gamma_{jt} \times \sigma_t^{-1} \) and \( \tilde{y}(\rho_{t}^{(s)}) = \left( \tilde{y}_{i1}(\rho_{t}^{(s)}), \ldots, \tilde{y}_{iN}(\rho_{t}^{(s)}) \right) \) as the vector of spatial lags depending on the current value of \( \rho_{t}^{(s)} \), with \( \sigma_t^2 \) referring to the clustered error variance assigned to industry \( i \), and set \( \tilde{\epsilon}_t = (y_{it} - \alpha_i - x_{it}'\beta_i) \times \sigma_t^{-1} \), where we again stack these quantities in \( \tilde{\epsilon}_t = (\tilde{\epsilon}_{1t}, \ldots, \tilde{\epsilon}_{Nt})' \). Let

\[
L\left(\rho_{t}^{(s)}\right) = \text{det}(I_N - \rho_{t}^{(s)}W) \times \exp\left\{ -0.5 \left( \tilde{\epsilon}_t - \tilde{y}(\rho_{t}^{(s)}) \right)' \left( \tilde{\epsilon}_t - \tilde{y}(\rho_{t}^{(s)}) \right) \right\},
\]

then the acceptance probability \( \varsigma \) of the proposal \( \rho_{t}^{(s)} \) implied by the likelihood is

\[
\varsigma = \min \left( \frac{L\left(\rho_{t}^{(s)}\right)}{L\left(\rho_{t}^{(s-1)}\right)}, 1 \right).
\]

The candidate draw \( \rho_{t}^{(s)} \) is accepted with probability \( \varsigma \), while in the opposite case, we retain the previous draw \( \rho_{t}^{(s-1)} \). After obtaining the full history for \( \rho_t \), it is easy to simulate the variance \( \varsigma^2 \), and the latent binary indicator \( \delta \). The conditional posterior of \( \delta = 1 | \varsigma^2 \) is given by

\[
\delta = 1 | \varsigma^2 \sim \mathcal{BER}\left(u_1 / (u_0 + u_1)\right),
\]

\[
u_1 = B_1^{-1/2} \exp\left\{ -\varsigma / 2B_1 \right\} p,
\]

\[
u_0 = B_0^{-1/2} \exp\left\{ -\varsigma / 2B_0 \right\} (1 - p).
\]

Conditional on the latent binary indicator \( \delta \) and the full history of the spatial dependence parameter, it can be shown that the conditional posterior distribution of \( \varsigma^2 \) is a generalized inverse Gaussian distribution. The parameter can thus be drawn using

\[
\varsigma^2 | \delta, \rho_1, \ldots, \rho_T \sim \mathcal{GIG}\left((1 - T)/2, \sum_{t=2}^{T} (\rho_t - \rho_{t-1})^2, (\delta B_1 + (1 - \delta)B_0)^{-1}\right).
\]

This completes the section on model estimation. We proceed by applying the proposed econometric framework to a study of time-varying effects in the transmission of US monetary policy shocks through the production network.
5. NETWORK EFFECTS OF US MONETARY POLICY

5.1. Data and model specification

For the sake of brevity, we only provide a brief overview of the data and refer to Ozdagli and Weber (2017) for more details. The event returns for industries used as dependent variables $y_{it}$ are constructed based on returns for all common stocks trading on the NYSE, Amex or Nasdaq around press releases by the Federal Open Market Committee (FOMC). In particular, the dependent variable is defined as the difference between the last trade observation before and the first observation after the event window.

To establish the cross-sectional dependency structure via the weighting matrix $W$, following Ozdagli and Weber (2017) we use input-output (IO) tables capturing dollar trade flows between industries published by the Bureau of Economic Analysis and the United States Department of Commerce. Industries $i$ for $i = 1, \ldots, N$ are aggregated at the four-digit IO-level, resulting in $N = 89$ cross-sectional units over time. Due to missing values, we augment the baseline Gibbs sampling scheme with an additional step for imputing these values in a Bayesian fashion (see, for instance, Gelman et al., 2013).

As exogenous measure of the monetary policy shocks, we rely on high-frequency changes in Federal funds futures featured in Gorodnichenko and Weber (2016). The predetermined nature of monetary policy announcement dates (eight regular FOMC meetings per year), combined with high-frequency data on forward-looking financial instruments in a tight window of 30 minutes around the press release allows for extracting the surprise component of the monetary policy action. The tight window around the announcement reduces the risk of other events than monetary policy affecting futures prices and provides support for the claim of exogeneity (see also Gürkaynak et al., 2005; Altavilla et al., 2019).\footnote{Concerns of central bank information shocks accompanying the monetary policy announcement biasing the effects caused by pure monetary policy shocks (see Nakamura and Steinsson, 2018; Jarociński and Karadi, 2019), can be neglected for the employed dataset (for details, see Ozdagli and Weber, 2017).}

The vector $x_{it}$ in Eq. (1) thus collapses to a scalar $x_t$ that is common to all $i$, while $\beta_i$ is the associated observation-specific parameter capturing the sensitivity of industry $i$ to the monetary policy shock. Moreover, we include an industry-specific intercept term $\alpha_i$. The information set includes data on FOMC announcements between early 1994 and late 2008, that is, $T = 121$.

5.2. Empirical results

First, we assess the importance of allowing for cross-sectional heterogeneities across industries. For this purpose, we estimate restricted versions of the general model proposed in Eq. (1) reflecting the empirical approaches of Bernanke and Kuttner (2005), Gürkaynak et al. (2005) and Ozdagli and Weber (2017). Second, we provide a discussion of the main findings of this paper resulting from relying on a time-varying spatial dependence specification.
Table 1: Estimated impacts of monetary policy on stock returns across industries.

|                | BK2005/GSS2005          | Ozdagli and Weber (2017) |
|----------------|-------------------------|--------------------------|

|                | (0.224,0.418) | (0.001,0.092)  |              |               |

Notes: The numbers refer to the estimated posterior median with the 1st and 99th percentile of the posterior distribution in parentheses. Benchmark specifications are provided by the similar setups in Bernanke and Kuttner (2005), Gürkaynak et al. (2005), abbreviated by BK2005 and GSS2005 respectively, and Ozdagli and Weber (2017). “Homogeneous” refers to pooling information deterministically across industries, while “heterogeneous” indicates industry-specific estimates. For the models featuring heterogeneous coefficients, we take the arithmetic mean over all industries per iteration of the algorithm and report the resulting posterior percentiles.

Nested specifications and benchmarks

Table 1 displays the results for restricted versions of our model. In particular, the columns labeled BK2005/GSS2005 correspond to econometric frameworks of Bernanke and Kuttner (2005), Gürkaynak et al. (2005), disregarding cross-sectional dependency structures and network effects (that is, \( \rho_1 = \ldots = \rho_T = 0 \)). The columns labeled Ozdagli and Weber (2017) feature spatial econometric models without time variation (that is, \( \rho_1 = \ldots = \rho_T \)). A further distinction is provided by estimating the model with homogeneous and heterogeneous coefficients. Here, “homogeneous” refers to pooling information deterministically across industries, that is \( \theta_1 = \ldots = \theta_N \), while “heterogeneous” indicates industry-specific estimates for \( i = 1, \ldots, N \).

For the models featuring heterogeneous coefficients, we take the arithmetic mean over all industries per iteration of the algorithm and report the resulting posterior percentiles (the posterior median, the 1st and 99th percentile), providing a measure of the average impact of monetary policy shocks on heterogeneous industry returns.

Negative coefficients \( \beta \) imply stock market responses in line with standard economic theory. Monetary tightening induces a reduction of future expected dividends, and by basic asset pricing theory, higher interest rates increase the discount rate of future dividends, resulting in stock market declines. Considering the first column of Tab. 1, a one percentage point surprise increase of the federal funds rate translates to a decline in stock market returns of about 1.2 percentage points with the 98 percent credible set ranging from approximately −0.9 to −1.5 percentage points.
This example also serves to illustrate the correspondence between interpretation of spatial econometric models and standard linear regressions, with obtained direct, indirect and total effects directly reflecting the regression coefficient due to the assumption of independent and identically distributed error terms. Compared to the findings of Bernanke and Kuttner (2005) and Gürkaynak et al. (2005), our estimates are rather small. Note, however, that the empirical findings are not directly comparable, due to their focus on the aggregate S&P 500 rather than industry-specific returns, and a different sampling period. Relaxing the assumption of parameter homogeneity, we find that the effects are roughly twice as large, where a one percent surprise in the federal funds futures causes stock returns to decline by roughly 2.4 percentage points, on average across industries. We focus on heterogeneities over the cross-sectional dimension in the next section.

Turning to the analysis of network effects, we find that the estimated effects for the spatial econometric specification with pooled coefficients are smaller than those obtained by Ozdagli and Weber (2017), for two reasons. First, our proposed framework directly imputes missing values using Bayesian techniques, and thus accounts for selection bias and adequate uncertainty quantification. Second, in contrast to Ozdagli and Weber (2017) we impose the restriction $w_{ii} = 0$ to guarantee the stability of the model.\(^8\)

The estimated total effects for the homogeneous specification are roughly in line with the effects estimated from a non-spatial model. Higher-order spillover dynamics explain roughly 33 percent of the total effects, with the posterior credible set ranging from 22 to 41 percent. An interesting finding is that when allowing for heterogeneous coefficients across industries, the obtained effects are roughly in line with the non-spatial specification of negative effects around 2.4 percentage points, while the estimated share of network effect contributions lies between 0.1 and 9.1 percent, with a posterior median of 1.6 percent. This finding suggests that disregarding heterogeneous effects across industries by pooling coefficients is consequential for the parameter $\rho$ that adjusts to reflect idiosyncrasies in direct effects and biases estimates for network effects.

**Allowing for time-varying spatial dependence and cross-sectional heterogeneity**

In the following, we discuss our findings for the full model featuring time-varying spatial dependence and cross-sectional heterogeneities. Given the importance of industry-specific idiosyncrasies identified in Tab. 1, we begin by discussing our findings for the heterogeneous regression coefficients. The mixture model provides substantial support for one common cluster, however, roughly in 25 percent of the draws we find evidence for two clusters. Differences mainly originate from idiosyncrasies in the sensitivity of industries to the monetary policy shocks, while the intercept terms $\alpha_i$ are pushed more strongly towards their common mean. The error variances $\sigma_m^2$ are heavily shrunk towards homogeneity.

Figure 1 shows the distribution of the posterior medians across industries in form of a boxplot. The upper panel displays the intercept $\alpha_i$, while the middle panel depicts the coefficients $\beta_i$.\(^9\)}

\(^8\) Disregarding this restriction, as in Ozdagli and Weber (2017), results in upward bias of the estimated network effects due to the lack of convergence of the Neumann series expansion of the impact matrix $(I_N - \rho W)^{-1} = \sum_{i=1}^{\infty} \rho^i W^i$. Our results are comparable to the provided robustness check in their paper where the main diagonal of $W$ is set to zero, accounting for posterior uncertainty of the estimates.

\(^9\)
associated with the monetary policy shock. Starting with the intercept coefficients $\alpha_i$, half of the industries exhibit estimates between $-0.05$ and $0.01$. This implies that the average return across industries around FOMC announcements is negative. Some few industries exhibit positive responses, however, these observations typically feature large posterior uncertainty surrounding the median. A substantially larger number of industries exhibit more pronounced negative estimates.

Turning to the industry-specific impacts of monetary policy surprises captured by $\beta_i$, we find that the median across industries is approximately $-1.3$ percentage points in response to a one percentage point increase in the instrument. This is roughly in line with our findings for the non-spatial specification featuring homogeneous coefficients in Tab. 1. As discussed in the context of how to interpret spatial models, however, the regression coefficients cannot be interpreted directly. For this purpose, we calculate the total effect per region which corresponds to the row sums of $S_{kt}$ depicted in the bottom panel of Fig. 1. For simplicity, we consider the average effect over time and refer to the following paragraphs for information on time-variation of the estimates. The median impact across industries and over time to a one percent surprise increase in federal funds futures around Fed announcements is about $-1.9$ percentage points, with half of the industries showing declines in stock returns between $-1.3$ to $-2.4$ percentage points. We find that effects for all industries are negative, with a substantial number exhibiting effects higher than $-2.5$ up to more than $-5$ percentage points. Considering hypothetical responses to a surprise 25 basis points interest rate hike, this implies that a number of industries shows stock market return declines exceeding 0.75 percent.

**Fig. 1:** Posterior median of the regression coefficients across industries.

*Note:* The solid black line indicates the median of the estimated posterior medians across industries, while the box covers the 25th and 75 quartile. Individual lines denote industries.
We proceed with discussing our findings for time-varying spatial dependence. Figure 2 shows the evolution of $\rho_t$ over time. The solid black line indicates the posterior median, alongside the 98 and 90 percent credible sets in shaded blue. FOMC announcement dates are indicated by the black vertical lines. Inference on the binary indicator dictating time variation shows that likelihood information strongly suggests time-varying spatial dependence, with $\delta = 1$ for all iterations of the sampling algorithm, translating into substantial differences in the parameter over time.

Fig. 2: Time-varying spatial dependence parameter.

*Note:* The solid black line indicates the posterior median, alongside the 98 and 90 percent credible sets in shaded blue. FOMC announcement dates are indicated by the black vertical lines.

Interestingly, higher importance of spatial dependence appears to occur during recessions. Relevant recessionary episodes for the employed dataset identified by the *NBER Business Cycle Dating Committee* are the mild recession between March and November 2001, and the global financial crisis and subsequent Great Recession from December 2007 to June 2009. Largest magnitudes for $\rho_t$ are detected during the Great Recession, with median estimates of roughly 0.55, followed by the first recession in the sample in early 2001 of approximately 0.4. The initial period covered by the sample is characterized by small contributions of spatial effects, with median estimates just below 0.2, while the time between the two recessions exhibits a spatial dependence parameter around 0.25 increasing gradually towards the outbreak of the global financial crisis.

It remains to quantify the overall importance of the network effects over time. Figure 3 shows the posterior distribution of the estimated total effects in the upper panel, while the lower panel depicts the relative share of indirect effects in percent. Movements in the strength of spatial dependence observed in Fig. 2 clearly translate to changes in the role of network effects of monetary transmission channels. The upper panel of Fig. 3 suggests that we do not only observe substantial difference over the cross-section, but also over time. In particular, the effect size before the first, and between the two recessions covered by the sample roughly correspond to the average effect of monetary policy surprises over time of about $-1.9$. The recessionary episodes, however, exhibit larger effects up to three percentage points on average caused by a
contractionary one percent policy surprise in the federal funds futures. Considering the lower panel of Fig. 3, we find that not only effect sizes are larger during recessions, but also that network effects tend to increase. During the recession of 2001, about 40 percent of the total effect sizes can be attributed to spillover effects, while this effect increases to approximately 60 percent during the Great Recession. This result links our findings to Kastner (2019), who finds pronounced increases in co-movement across industries during periods of economic turmoil. Expansionary economic episodes, on the other hand, show muted network effects with magnitudes of roughly 20 to 30 percent.

Fig. 3: Total effects of monetary policy shocks and share attributed to network effects.  
*Note:* The solid black line indicates the posterior median, alongside the 98 and 90 percent credible sets in shaded blue.

6. CLOSING REMARKS

This paper studies the importance of spillover effects in the transmission of monetary policy shocks through the US production network. We propose a novel Bayesian spatial panel state-space model to capture time-variation in the magnitude of network effects. Moreover, we address industry specific heterogeneities via a sparse finite Gaussian mixture prior on the model coefficients. Our results suggest substantial differences in industry responses, and identify recessionary episodes as periods where network effects play a crucial role.

A. POSTERIORS FOR MIXTURE-SPECIFIC QUANTITIES

For simplicity we suppress observation-specific intercepts \( \{\alpha_i\}_{i=1}^N \) in Appendix A. Conditional on the observation-specific coefficients \( \{\beta_i\}_{i=1}^N \), variances \( \{\sigma^2_i\}_{i=1}^N \) and the group-allocation indicators \( \{\eta_i\}_{i=1}^N \), the posteriors for the prior mean and covariance matrix are independent from the data and can be drawn using standard results from linear regression models (see, for instance, Koop, 2003).

Given draws for the group-allocation indicators \( \eta = \{\eta_i\}_{i=1}^N \), the posterior distribution of the mixture probabilities follows a Dirichlet distribution:

\[
\rho | \eta \sim \mathcal{D}(\kappa_1, \ldots, \kappa_M).
\]

Here, we define \( \kappa_m = \kappa + N_m \) with \( N_m \) referring to the number of industries assigned to cluster \( m \). Conditional on the group means \( \{\mu_m\}_{m=1}^M \), the common prior prior covariance matrix \( V \) and the mixture weights \( \omega \), the regime indicators \( \eta \) follow a multinomial distribution with

\[
\Pr(\eta_i = m | \omega_m, \mu_m, V) \propto \omega_m f_N(\beta_i | \mu_m, V), \quad \text{for } m = 1, \ldots, M.
\]

The full conditional posterior of \( \mu = \text{vec}(\mu_1, \ldots, \mu_M) \) follows a multivariate Gaussian distribution with diagonal covariance matrix:

\[
\mu | V, \eta, \mu_0, V_0 \sim N\left(\mu, \frac{1}{M} V_0\right).
\]

with the posterior variance and mean given by,

\[
\begin{align*}
\overline{V}_\mu &= (V^{-1} \otimes H' H + \sum_{m=1}^M V_0^{-1})^{-1}, \\
\mu &= \overline{V}_\mu \left( V^{-1} \otimes H' \beta + \sum_{m=1}^M V_0^{-1} \mu_0 \right).
\end{align*}
\]

Here, \( H \) is a \( N \times M \) matrix with \( i \)th row given by \( H_i = (I(\eta_i = 1), \ldots, I(\eta_i = M)) \), \( \beta = (\beta_1, \ldots, \beta_N)' \) is a \( KN \)-dimensional vector and \( \iota_M \) is a \( M \)-dimensional vector of ones.

Conditional on \( V_0 \) and \( \mu \), the conditional posterior distribution of the common mean \( \mu_0 \) reads as:

\[
\mu_0 | V_0, \mu \sim N\left(\frac{\sum_{m=1}^M \mu_m}{M}, \frac{1}{M} V_0\right).
\]

The final ingredients for the location mixture are the shrinkage parameters \( l_1, \ldots, l_K \). Conditional on \( R \) and \( \mu \) the conditional posterior distribution is given by:

\[
l_j | R, \mu \sim GIG\left(\epsilon_0 - M/2, 2\epsilon_1, \frac{\sum_{m=1}^M (\mu_{mj} - \mu_{0j})^2}{R_j}\right),
\]

with \( \mu_{mj}, \mu_{0j} \) and \( R_j \), for \( m = 1, \ldots, M \) denoting the \( j \)th element of the component-specific means, common mean and of \( R \), respectively.

Finally, we sample \( \sigma^2_m \), for \( m = 1, \ldots, M \) from an inverse gamma conditional posterior distribution given by

\[
\begin{align*}
\sigma^2_m \mid \bullet & \sim G^{-1}(\xi_m, \Xi_m) \\
\Xi_m &= \Xi + \frac{1}{2} \sum_{i} (y_i - x_i' \beta_i - \alpha_i)'(y_i - x_i' \beta_i - \alpha_i), \\
\xi_m &= \xi + TN_m/2.
\end{align*}
\]
The common scaling indicator $\Xi_m$ is also drawn from an inverse gamma conditional,

$$\Xi|\{\sigma^2\}_{m=1}^M, \Psi, \psi \sim G^{-1}(\overline{\psi}, \overline{\Psi})$$

$$\overline{\Psi} = \Psi + \sum_{m=1}^M \sigma_m^{-2},$$

$$\overline{\psi} = \psi + M\xi.$$

B. MCMC ALGORITHM

The set of conditional posterior distributions in Section 3 and Appendix A is used to generate draws for all parameters of the model by a standard MCMC sampling algorithm. Specifically, the sampler iterates through the following steps:

1. Sample the observation-specific regression coefficients $\beta_i$ on an equation-by-equation basis. The posterior takes a standard form (see, for instance Koop, 2003) conditional on the full history of the spatial parameter $\{\rho_t\}_{t=1}^T$.

2. Given draws for the observation-specific coefficients $\{\beta_i\}_{i=1}^N$, variances $\{\sigma^2_i\}_{i=1}^N$ and the group-allocation indicators, the posteriors for the prior mean and covariance matrix are independent from the data. For the corresponding posterior distributions and moments, see Appendix A and Malsiner-Walli et al. (2016).

3. Conditional on $\{\beta_i\}_{i=1}^N$ and the group-allocation indicators, the posterior for the cluster-specific variances $\{\sigma^2_i\}_{i=1}^N$ can be sampled based on the quantities provided again in Appendix A and Malsiner-Walli et al. (2016).

4. Obtaining draws for the full history of the spatial dependence parameter $\rho_t$ is achieved by employing the proposed Metropolis-Hastings algorithm in Section 3.

5. Conditional on $\{\rho_t\}_{t=1}^T$ it is easy to sample the process variances $\varsigma^2$. Given $\varsigma^2$, a draw from the posterior of the binary indicator $\delta$ that governs time-variation is obtained using the corresponding posteriors Section 3.

6. Given a draw for all model parameters, it is straightforward to obtain a draw for the missing values in the dependent variable (Gelman et al., 2013).

This completes the MCMC algorithm employed to simulate from the posterior distribution. After choosing starting values and a sufficient burn-in period we store draws from the conditional posterior distributions. In particular, we discard the initial 4,000 draws, while Bayesian inference is performed based on each third of the subsequent 6,000 draws resulting in a set of 2,000 draws from the posterior.
