I. INTRODUCTION

Interacting electrons in one spatial dimension (1D) are one of the best examples of strongly correlated fermionic systems. They are usually discussed in terms of the Tomonaga-Luttinger liquid (TLL) theory. We use explicitly the charge fractionalization scheme which results from the chiral symmetry of the model. We suggest that results of the standard two-terminal (2T) conductance measurement depend on the coupling of TLL with the reservoirs and can be interpreted as different boundary conditions at the interfaces. We propose a three-terminal (3T) geometry in which the third contact is connected weakly to the bulk of TLL subjected to a large bias current. We develop a renormalization group (RG) analysis for this problem by taking explicitly into account the splitting of the injected electronic charge into two chiral irrational charges. We study in the presence of bulk contact the leading order corrections to the conductance for two different boundary conditions, which reproduce in the absence of bulk contact, respectively, the standard 2T source-drain (SD) conductance $G_{SD}^{(2)} = e^2/h$ and $G_{SD}^{(2)} = ge^2/h$, where $g$ is the TLL charge interaction parameter. We find that under these two boundary conditions for the end contacts the 3T SD conductance $G_{SD}^{(3)}$ shows an UV-relevant deviation from the above two values, suggesting new fixed points in the ohmic limit. Non-trivial scaling exponents are predicted as a result of electron fractionalization.

Excitations are created in chiral pairs with one excitation moving to the left and the other to the right; the charges carried by each possible pair of states form a 2D manyfold $(Q_+, Q_-)$, where $Q_\pm = \frac{1}{2}(N \pm gJ)$ with $N$ and $J$ being integers having the same parity: $(-1)^N = (-1)^J$. $N$ and $J$ are standard zero-mode quantum numbers associated, respectively, with the total charge and the persistent current of the system. $g$ is the so-called TLL parameter, which contains all the relevant information of the electron-electron interaction. $g$ takes the value, $0 < g < 1$ for a standard repulsive interaction, whereas $g = 1$ for non-interacting 1D fermions.

The main question to be asked is whether or not these irrational charge excitations are observable. Consider an electron incident in the middle of TLL either of infinite length or sufficiently far away from the boundaries so that the chiral symmetry be preserved. The injected electron splits into two eigen excitations which have irrational charges $Q_+ = (1 + g)/2$, $Q_- = (1 - g)/2$ (or vice versa), and propagate in opposite directions. This picture is quite reminiscent of a three-terminal conductance measurement in which the third terminal is attached to the middle of QW connected to the source (S) and drain (D) (See Fig. 1). The main findings of this paper are that the standard conductance measurement done in this geometry does provide some information on the charge fractionalization. More precisely, we consider a source-drain (SD) conductance $G_{SD}^{(3)}$, under a large bias current $I_{bias}$ circulating through the QW between S and D, and in the presence of bulk-injected current $i_{bulk}$. The third terminal, or a bulk contact, at voltage $V$ is then connected by an ohmic wire either to the S or to the D. We consider the case of small $i_{bulk}$, i.e., the case in which $-eV$ is close to the chemical potential of the reservoir from which $i_{bulk}$ is
provided. We find under these circumstances \(G_{SD}^{(3)}\) is subjected to a change characterized by unusual scaling exponents which take different values depending on \(G_{SD}^{(2)}\) in the absence of \(i_{\text{bulk}}\). In Sec. III we will explain in length that different values of \(G_{SD}^{(2)}\) can be interpreted as different boundary conditions at the end contacts to S and D. In this paper, we highlight two specific boundary conditions which correspond to \(G_{SD}^{(2)} = e^2/h\) (↔ boundary condition A) and \(G_{SD}^{(2)} = ge^2/h\) (↔ boundary condition B). In these terms we found a non-trivial scaling exponent \((2\Delta)^2 - 1\) (See Eq. (29)) under a specific boundary condition A, whereas a standard scaling exponent \(2\Delta - 1\) (See Eq. (29)) for boundary condition B, which is simply related to the anomalous scaling dimension \(\Delta\) of the TLL electron operator. This result is a remarkable consequence of electron fractionalization under a stationary bias current \(I_{\text{bias}}\).

A motivation of this paper is therefore closely related to the so-called "conductance puzzle" of the QW: an apparent contradiction among different theoretical and experimental results for the two-terminal (2T) conductance \(G_{SD}^{(2)}\) in the ohmic regime. In spite of the theoretical prediction that the interaction should renormalize the conductance as \(G_{SD}^{(2)} = ge^2/h\) [8] one of the first conductance measurements on a QW by Tarucha et al. has found a non-renormalized universal conductance \(G_{SD}^{(2)} = e^2/h\) for an interacting system. On the contrary, in the case of the fractional quantum Hall (FQH) edge mode, an example of a chiral TLL [10], the Hall conductance, usually measured in a four-terminal geometry, is maximally renormalized at a topological number: \(G_H = \nu e^2/h\) [11].

It turns out that a rapidly growing number of experimental results is now available, on the conductance of QW and of carbon nanotubes. Carbon nanotubes have been expected since their discovery to be ideal 1D quantum wires. The single-walled nanotubes (SWNT) have four conducting channels indicating an expected quantized conductance: \(G_{SD} = 4e^2/h\) [21]. The ballistic transport in carbon nanotubes was first observed in only one channel of multi-walled nanotubes (MWNT) with \(G_{SD} \sim 2e^2/h\) [24]. The temperature and bias voltage dependence of the conductance reported in Ref. [13] do suggest that this system is a strongly correlated 1D electronic liquid. The TLL theory for carbon nanotubes [24] has suggested an interaction parameter \(g\) in the range \(0.2 - 0.3\).

Recent data on the conductance of QW and carbon nanotubes display a variety of results. In Ref. [24] significant deviations from the quantized value \(e^2/h\) were observed. In Ref. [17], the observed conductance exhibits fluctuations versus Fermi energy approaching the unrenormalized theoretical value \(4e^2/h\) as the temperature is lowered. On the other hand, in the experiment by Kasumov et al. [18] the isolated SWNT exhibits a resistance which saturates at low temperature (in the presence of a sufficiently intense magnetic field) to a factor of about 0.25 times the expected unrenormalized value. In our route to suggesting experimental ways of observing irrational excitations, we had to spend some time trying to understand this variety of results. Our understanding, as explained in the body of this paper, is that two terminal conductance measurements should indeed display this variety of results, which may be understood as expressing a variety of boundary conditions at the end contacts.

The main effort of this paper is devoted to studying more involved experimental geometries than two terminal ones. To our knowledge the only way to describe injection of electrons in a QW through a weak bulk contact is to resort to the irrational excitation picture, which should be taken into account in the theoretical description of this process. Thus, examining electron injection, from one (various) weak bulk contact(s), in a QW connected to reservoirs at its ends, should lead to specific experimental predictions, as we argue in the body of this work. We were stimulated in that direction by the work of Chamon and Fradkin. That work deals with the FQH effect and examines the conductance of a FQH bar (See Sec. III-C). In the case of the non-chiral liquid, one cannot easily manufacture electrical contacts which inject electrons only in one chiral eigen-mode of the TLL Hamiltonian density, so that one cannot use the results of [24]. One must actually solve the problem of the non-chiral TLL with many leads.

We derive new scaling exponents associated with the currents injected from bulk contacts. More generally we discuss effects which are derived using the irrational excitation picture, allowing measurements of \(g\) through multi-terminal conductance measurements. Deviations from the unrenormalized perfect conductance value are predicted in the ohmic limit. In the renormalization group (RG) picture this naturally suggests a possibility of new intermediate fixed points. We have not been able, though, to prove that our results are unique predictions of the irrational excitation scheme, so that experimental observation of, say, the new scaling exponent mentioned above would be at best a plausibility argument in favour of this scheme. The discussion of shot-noise experiments is also left for a future publication.

This paper is organized as follows: Sec. II describes the model we are studying. That section is an attempt to clarify the notion of the chemical potential for (interacting) eigen-modes, as opposed to the chemical potential for bare electrons. Sec. III discusses equilibration of 1D conductors with the 3D reservoirs: in actual experiments, which are the particles which equilibrate with the reservoirs: the bare electrons, or the eigen-modes of the TLL? This analysis allows a physical interpretation of our boundary conditions. In Sec. IV we solve our chiral electric circuit equations using the technology developed in Sec. III. Sec. V is devoted to the RG analysis of a bulk contact. Using our fractional scaling analysis, we demonstrate that a non-trivial scaling exponent appears
as a result of a specific boundary condition (boundary condition A). Sec. VI is a generalization to many bulk contacts. Some remarks on the application to SWNT and MWNT will be found in Sec. VII. Our conclusions are discussed in Sec. VIII.

II. MODEL, NOTATIONS AND CHIRAL DENSITIES

Of importance to us in this paper is the distinction to be made between bare chiral electron densities and eigen-modes chiral densities of the TLL. The bare chiral electron densities \( \rho^{(0)}_\pm(x, t) \) correspond to the densities of electrons created either at the left or right Fermi points of a non-interacting system. The total electronic density \( \rho(x, t) \) and the current density \( j(x, t) \) are related to \( \rho^{(0)}_\pm(x, t) \) as \( \rho(x, t) = \rho^{(0)}_+ + \rho^{(0)}_- \), \( j(x, t) = v_F (\rho^{(0)}_+ - \rho^{(0)}_-) \). In the non-interacting system the bare chiral electron densities are indeed two independent eigenmodes of the system: \( \rho^{(0)}_\pm(x, t) = \rho^{(0)}_\pm(x + v_F t) \). It is however no longer true in the TLL. In the interacting system the left and right-moving electrons of the non-interacting system are strongly coupled together; accordingly, the bare electronic densities are no longer chiral. In order to clarify this point we consider the harmonic hamiltonian density of the spinless TLL,

\[
H_{\text{TLL}} = \frac{u}{2} \left[ \frac{1}{g} \left( \frac{\partial \Phi(x, t)}{\partial x} \right)^2 + g \Pi(x, t)^2 \right],
\]

(1)

where we have introduced the standard phase field \( \Phi \) related to the electron density by: \( \rho(x, t) = \frac{1}{\sqrt{\pi}} \frac{\partial \Phi(x, t)}{\partial x} \), and its conjugate canonical momentum \( \Pi(x, t) \). \( u = v_F/g \) is the dressed velocity. Note also that the continuity equation shows that the current density is simply: \( j(x, t) = -\frac{1}{\sqrt{\pi}} \frac{\partial^2 \Phi(x, t)}{\partial t} \). The stationary components of \( \rho(x, t) \) and \( j(x, t) \) are the zero modes: \( N = \int_{-L/2}^{L/2} \rho(x, t) \), \( J = \int_{-L/2}^{L/2} j(x, t) \), which obey the fermionic selection rule \( (-1)^N = (-1)^J \) \([4]\). Using Hamilton equations: \( u g \Pi(x, t) = \frac{\partial \Phi(x, t)}{\partial t} \), \( u \frac{\partial^2 \Phi(x, t)}{\partial x^2} = \frac{\partial \Pi(x, t)}{\partial t} \), one finds immediately

\[
\left( \frac{\partial}{\partial x} + \frac{1}{u} \frac{\partial}{\partial t} \right) \left[ \frac{\partial \Phi(x, t)}{\partial x} \pm g \Pi(x, t) \right] = 0.
\]

(2)

This shows that \( \rho^{(0)}_\pm(x, t) = \frac{1}{2\sqrt{\pi}} \left[ \frac{\partial \Phi(x, t)}{\partial x} \pm g \Pi(x, t) \right] \) are indeed chiral eigenmodes of the system: \( \rho(x, t) = \rho^L(x + ut) \). Observing that \( \rho(x, t) = \rho_+ + \rho_- \), \( j(x, t) = u (\rho_+ - \rho_-) \), one concludes that \( \rho_+ \) and \( \rho_- \) correspond to a different decomposition of the total density into chiral densities from the non-interacting case. These eigenmode chiral densities mix both left and right moving electrons, since the bare chiral densities (obtained when \( g = 1 \) are: \( \rho^{(0)}_{\pm} = \frac{1}{2\sqrt{\pi}} \left[ \frac{\partial \Phi(x, t)}{\partial x} \pm \Pi(x, t) \right] \). In terms of these eigenmode chiral densities obeying the anomalous Kac-Moody commutation relations, the hamiltonian density splits into two commuting chiral parts: \( H = \frac{u}{2g} \rho^2_+ + \frac{u}{2g} \rho^2_- = H_+ + H_- \). The stationary component of \( \rho_{\pm}(x, t) \) are nothing but the chiral charges \( Q_\pm = \int_{-L/2}^{L/2} \rho_{\pm}(x, t) \) \([27]\). It is convenient to introduce a vector notation for the chiral densities. The dressed eigenmode density \( \tilde{\rho} = \begin{bmatrix} \rho_+ \\ \rho_- \end{bmatrix} \) is related to the bare density \( \tilde{\rho}^{(0)} = \begin{bmatrix} \rho^{(0)}_+ \\ \rho^{(0)}_- \end{bmatrix} \) in the matrix equation as \( \tilde{\rho} = \Omega \tilde{\rho}^{(0)} \),

where the matrix \( \Omega = \frac{1}{2} \begin{bmatrix} 1 + g & 1 - g \\ 1 - g & 1 + g \end{bmatrix} \) characterizes the fractionalization of electronic charge \(-e\).

In the absence of applied external voltage \( V_S - V_D \) the average current \( I = \langle j(x, t) \rangle \) is zero. In order to drive a net current through the sample, let us allow for independent variations of the left and right bare chemical potentials. The possibility to adjust them independently expresses the chiral separation of TLL. This is accomplished by adding a chemical potential to the hamiltonian. But once again a distinction should be made between bare chemical potentials \( \tilde{\mu}^{(0)} = \begin{bmatrix} \mu^{(0)}_+ \\ \mu^{(0)}_- \end{bmatrix} \) corresponding to a variation of the bare electron densities and eigenmode chemical potentials \( \tilde{\mu} = \begin{bmatrix} \mu^+ \\ \mu^- \end{bmatrix} \) corresponding to the eigen-mode chiral densities. More precisely, \( \tilde{\mu}^{(0)} \) and \( \tilde{\mu} \) are defined, respectively, by minimizing

\[
H_{\text{TLL}} - \mu^{(0)}_+ \rho^{(0)}_+ - \mu^{(0)}_- \rho^{(0)}_- = \frac{u\pi}{2g} \tilde{\rho}^{(0)T} \Omega^2 \tilde{\rho}^{(0)} - \tilde{\mu}^{(0)T} \tilde{\rho}^{(0)},
\]

\[
H_{\text{TLL}} - \mu_+ \rho_+ - \mu_- \rho_- = \frac{u\pi}{2g} \tilde{\rho}^{T} \tilde{\rho} - \tilde{\mu}^{T} \tilde{\rho}.
\]

Completing the square densities, one finds \( \tilde{\mu}^{(0)} = \frac{u\pi}{g} \Omega^2 (\tilde{\rho})^{(0)} \), \( \tilde{\mu} = \frac{u\pi}{g} (\tilde{\rho}) \Omega (\tilde{\rho})^{(0)} \) \([27]\). Comparing the two expressions, the relation between bare and dressed chemical potential is found to be \( \tilde{\mu}^{(0)} = \Omega \tilde{\mu} \).

Note that \( \tilde{\mu}^{(0)} \) and \( \tilde{\mu} \) obey the same linear transformation as the one for \( \tilde{\rho}^{(0)} \) and \( \tilde{\rho} \) except that the roles of bare electrons and of the chiral eigenmodes are exchanged.

It would be worth mentioning here that in the four-terminal conductance measurement by Piccietto et al. the resistance data (Fig. 3 of \([14]\)) shows that the chemical potential \( \mu \) coupled to additional probes (probe A and B) is neither bare nor dressed chiral chemical potentials. Instead the additional probes seem to be coupled almost equally to both chiralities; \( \mu \) is coupled to the total density: we should rather minimize the hamiltonian density \( H_{\text{TLL}} - \mu \rho \) to find \( \mu = \frac{u\pi}{2g} \). If the electronic transport through the conductor is perfectly balistic, this chemical potential \( \mu \) is uniform throughout the conductor, which explains the data of Piccietto et al.
In the presence of an electric field the chemical potential becomes an electrochemical potential and one may introduce the following chiral voltages: 
\[ \tilde{\mu}^{(0)} = -e\tilde{V}^{(0)} = \begin{bmatrix} -eV_+^{(0)} \\ -eV_-^{(0)} \end{bmatrix}. \]
They are related, of course, via the relation 
\[ \tilde{V} = \Omega \tilde{V}^{(0)}. \]
Thus the above boundary condition ensures the 2T SD boundary condition is indeed 
\[ V = \Omega V^{(0)}. \]

III. BOUNDARY CONDITIONS AT THE END CONTACTS — SCREENING AND EQUILIBRATION

In the approach developed by Landauer and Büttiker for non-interacting electrons, the chiral chemical potentials 
\[-eV_+, -eV_-\] of the bulk sample are equilibrated with that of the reservoir from which the electrons are injected [2]: 
\[ V_S = V_+, V_D = V_- \]
Whereas in the bulk the total current \( I \) is related to \( V_+, V_- \) as 
\[ I = \frac{e^2}{\hbar}(V_+ - V_-). \]
Thus the above boundary condition ensures the 2T SD conductance, usually defined as 
\[ G^{(2)}_{SD} = I/(V_S - V_D), \]
to be given by the standard unit conductance: 
\[ G^{(2)}_{SD} = e^2/\hbar. \]

Let us now switch on the interaction. As we have seen in the last section, the conductance of the system as measured against either the bare or e mode voltage yields therefore different values, e.g., if the conductance is measured between \( V_+ - V_- \), this gives the conductance \( ge^2/\hbar \) in the bulk, which is reminiscent of the four-terminal measurement in FQH bar [1]. In the case of the nonchiral liquid, a four-terminal measurement analogous to the one in Ref. [1] is difficult to realize, since one cannot easily manufacture electrical contacts which are coupled only to one of the chiral eigenmodes of TLL Hamiltonian. In the experiment by Piccitto et al. the resistance data (Fig. 3 of [3]) shows that the voltage probes (probe A and B) are coupled almost equally to both chiralities. On the other hand, if the conductance is measured, under certain circumstances, against \( V_+^{(0)} - V_-^{(0)} \), then it gives \( e^2/\hbar \). We believe that the value taken by the conductance, when the bulk sample is connected to the current reservoirs, is, a matter of coupling between the sample and the reservoirs. In the followoing we will formulate this in a more systematic way, i.e., in the form of boundary conditions at the end contacts.

A. Equilibration with bare electrons — Screening by a metallic gate

Let us first consider the boundary condition discussed in refs. [3,29,30,31]. This boundary condition has been labelled a “radiative” boundary condition in Ref. [3]. With this boundary condition the particles emitted by the left reservoir are then in equilibrium with the bare electrons:

\[
\begin{cases}
V_S = V_+^{(0)} = [1 0] \Omega \tilde{V} \\
V_D = V_-^{(0)} = [0 1] \Omega \tilde{V}.
\end{cases}
\]

where the matrix \( \Omega \) has been defined as

\[
\Omega = \frac{1}{2} \begin{bmatrix} 1 + g & 1 - g \\ 1 - g & 1 + g \end{bmatrix}.
\]

Let us first recall that the conductance defined with this boundary condition is indeed \( e^2/\hbar \) independently of \( g \). Recall the relation between bare and dressed voltages: 
\[ \tilde{V} = \Omega \tilde{V}^{(0)}. \]
The bias voltage \( V_S - V_D = [1, -1] \tilde{V}^{(0)} \) can be written as 
\[ V_S - V_D = [1, -1] \Omega \tilde{V} = g [1, -1] \tilde{V}, \]
where we have used \([1, -1] \Omega = g [1, -1]\). The total current \( I \) can be expressed either in terms of the bare bias voltages 
\[ I = \frac{e^2}{\hbar} [1, -1] \tilde{V}^{(0)} \] or in terms of the dressed eigenmode voltages as 
\[ I = \frac{e^2}{\hbar} [1, -1] \tilde{V}. \]
It then follows that the conductance is given by 
\[ G^{(2)}_{SD} = e^2/\hbar \] independently of \( g \).

Another important remark is that this boundary condition requires the existence of a metallic gate along the 1D sample [3,31]. When a certain amount of charge \( Q \) is injected from the reservoir through an end contact, the TLL system cannot screen this charge completely because of this boundary condition, instead 
\[ Q_{TLL} = -(1 - g^2)Q \] is induced in TLL. In order for the charge conservation \( Q + Q_{TLL} + Q_{gate} = 0 \) to be satisfied there needs to exist a metallic gate providing for a screening charge \( Q_{gate} = -g^2Q \) [31]. The existence of metallic gate also explains a short-range interaction in 1D quantum wire which ensures a finite parameter \( g \) of TLL model. In the experiment by Tarucha et al. [1] the 1D sample was indeed screened by the metallic gate.

B. Equilibration with dressed eigenmodes — No screening gate

Knowing that the boundary condition [3] requires the existence of metallic gate one naturally asks the question what will be the corresponding boundary conditions in the absence of screening by a metallic gate. TLL with finite \( g \) (long-range interaction cut off by the finite length
of the sample and the width of the tube) without screening
gate is indeed realized in a SWNT [21]. The boundary
condition which ensures \( Q + Q_{TLL} = 0 \) with no reference
to the metallic gate is, in fact, \( V_+ = V_S, V_- = V_D \). The
dressed eigenmode voltages are equilibrated with those
of the reservoirs, i.e., the particles emitted from the left
(right) reservoir are moving to the right (left) and are
in equilibrium with the right (left)-moving eigenstates
of the TLL. If this naive picture is indeed the case, the
conductance in terms of the voltage difference between
the reservoirs, i.e., the particles emitted from the left
is immediately from the relation
\[ I = g \sum_{\pm} [1, -1] V, \text{ i.e., } G_{SD}^{(2)} = ge^2/h. \] The conductance
is fully renormalized [26].

C. Intermediate possibilities

Are there intermediate possibilities, i.e., situations
where neither bare electrons nor eigenstates are in equi-
librium with the reservoir? In the case of FQH edge
mode, i.e., if one replaces in the above discussion the
1D TLL sample by a FQH bar at bulk filling factor \( \nu \), it
was shown in Ref. [24] that depending on the number \( N_L \)
(\( N_R \)) of left (right) strong point like contacts with the left
(right) reservoir the \( SD \) conductance of a FQH bar \( G_{SD} \)
varies from \( G_{SD} = e^2/h \) to \( G_{SD} = \nu e^2/h \). The first case
(boundary condition A) in which the \( 2T \) conductance is
not fractional but integral \( (G_{SD}^{(2)} = e^2/h) \) corresponds to
a single tunneling point contact: \( N_L = N_R = 1 \). The sec-
ond case (boundary condition B) where the \( end \) contacts
are in equilibrium with dressed eigenmodes corresponds
to an infinite number of tunneling point contacts between
each reservoir and the sample: \( (N_L, N_R) \to (\infty, \infty) \).
The third possibility (boundary condition C) arises in
between, when there is a finite number of tunneling quan-
tum point contacts.

Turning to the case of the quantum wire, which of these
two cases is relevant experimentally? A first model is
that of the inhomogeneous TLL, in which the reservoirs
are modeled as TLL at \( g = 1 \) (1D free fermions). [23]
We observe that this model implicitly describes a trans-
mission of the current through a single point contact.
Furthermore it implies the presence of a screening gate.
This confirms that a single contact between the reservoirs
is not enough for equilibration of the 1D sample with the
reservoirs as we surmised, yielding therefore an unrenor-
malized conductance. A second series of explanations
rely on the assumption that the conductance measured
is the ratio \( I/V_{loc} \) of the current to a so-called total local
field, which sums a contribution from the external electrical
field plus some response of the TLL, rather than the
ratio of the current to the external potential as usual [23].
It is then shown by a diagrammatical analysis that
the local field is \( E_{loc} = E_{ext}/g [23] \). The ratio \( I/V_{ext} \) being
assumed as in the initial work by Kane and Fisher [32] to
be equal to \( g \), this yields an unrenormalized conductance
\( I/V_{loc} = 1 \). That analysis is doubtful because experi-
mentally the external field is fixed which means that one
really measures the ratio \( I/V_{ext} \). By contrast, in our
approach what is measured is indeed the ratio \( I/V_{ext} = 1 \),
although we agree on the relation \( E_{loc} = E_{ext}/g \). Note
that this follows from elementary considerations on chiral
modes (see section II).

We stress that although the boundary condition A
seems to be realized in the experiments when a screen-
ing gate is present, this does not bar the possibility that,
in different set-ups, boundary condition B or C might
apply. In the experiment by Kasumov et. al. [17] the iso-
lated SWNT sample \( ST_1 \) exhibits a resistance \( R \) which
saturnes at high temperatures to \( R \sim 25k\Omega \) (see Fig.
2B of Ref. [17]). This corresponds to the conductance
\( G^{(2)}_{SD} \sim e^2/h \), which is smaller by a factor 1/4 than
\( G^{(2)}_{SD} = 4e^2/h \) expected from the boundary condition [8].
Note that this experiment was done in the absence of
screening gate, where the boundary condition B might
apply. Since \( g \) is typically in the range 0.2 to 0.3, the
observed conductance \( G^{(2)}_{SD} \sim e^2/h \) is indeed reminis-
cent of the renormalized conductance: \( G^{(2)}_{SD} = 4ge^2/h \).

The inhomogeneous TLL model [23] assumes by con-
struction an injection of current through a single end
contact for each reservoir. But the current might be in-
jected through bulk contacts in addition to being injected
through \( end \) contacts. In further sections of this paper we
address the issue of \( bulk \) contacts using the perturbative
RG analysis for bulk tunneling.

IV. ONE BULK CONTACT IN THE PRESENCE
OF A LARGE BIAS CURRENT

In the following we will consider a model where the
sample is connected to the reservoir not only through the
\( end \) contacts but also through some \( bulk \) contacts. For
the \( end \) contact, depending on the presence or absence
of screening gate, the boundary conditions (A) or (B) will
be applied. We will mainly focus on the case where the
two \( end \) contacts impose a large stationary current \( I_{bias} \)
in the quantum wire. In this case the additional current
injected through the \( bulk \) contact can be treated as a
small perturbation. We will develop later a RG analysis
which is compatible with fractionalization scheme, which
will tell us the scaling behavior of this bulk injected cur-
tent. In order to utilize the results of this fractional RG
analysis, we first have to derive and solve the equations
which describe our \( chiral electric circuits \). We will see
that the existence of a large stationary current as well as
different boundary conditions play an important role in
finding a new exponent in the conductance formula.

A motivation of our work is based on the findings of
Ref. [1]. Following the latter work, an electron injected
from a normal lead into a TLL splits into two eigen ex-
citations which are \( fractional \) (in fact, for most repulsive
interaction strengths, the correct term would be \( irra-
tional \)). Namely, the two chiral eigen excitations have
charges \((1 + g)/2, (1 - g)/2\), and they propagate in opposite directions with the corresponding chiral mode velocities.

Various authors have discussed the observability of those irrational excitations \(ge\) [2,36–39]. The obvious suggestion is based on electric current noise measurements [1]. However the results of Ref. [25] suggest that the parameter \(g\) might also be measured in a conductance experiment with many contact points, and/or possibly different bias voltages. This is what we proceed to do below, in various situations.

Let us first consider a single bulk contact in the middle of the sample. The bulk contact has the following two effects (see Fig. 1).

1. Tunneling of Laughlin quasiparticles [1] between the two chiral modes. This is due to the backward scattering between \(+k_F\) and \(-k_F\) electrons. The total charge is conserved in this process \((N = 0, J = \pm 2)\). When a macroscopic number of electrons are involved in this process, a current \(i_{\text{back}}\) is back-scattered from \((+)\)-chirality to \((-)\)-chirality:

\[
i_{\text{bulk}} = i_+ + i_-.
\]

2. Tunneling of electrons into or out of the bulk sample through the bulk contact, i.e., injection or ejection of electrons through the bulk contact. The total charge is increased or decreased by 1: \(N = \pm 1, J = \pm 1\), respectively, for the tunneling of \(+k_F\) \((-k_F)\) electrons. When a current \(i_{\text{bulk}}\) is injected through the bulk contact into the sample, it splits into two parts \(i_+\) and \(i_-\) corresponding, respectively, to an eigen mode with \((+)\)-chirality: \(i_{\text{bulk}} = i_+ + i_-\).

\[
\begin{align*}
V_L & \rightarrow \quad i_+ \quad \quad i_{\text{back}} \quad \quad i_- \quad \rightarrow \quad V_R \\
V_{Lg} & \rightarrow \quad V_{Lg} \quad \rightarrow \quad V_{Rg} \quad \rightarrow \quad V_R
\end{align*}
\]

**FIG. 1**. A bulk contact in the presence of a large stationary current \(I_{\text{bias}}\). The chiral symmetry of the TLL is not destroyed by the bulk contact. At the bulk contact a current \(i_{\text{back}}\) is back-scattered from \((+)\)-chirality to \((-)\)-chirality due to the tunneling of Laughlin quasiparticle. A net current \(i_{\text{bulk}}\) is injected through the bulk contact into the sample. As soon as it is injected into the TLL sample, it splits into two parts \(i_+\) and \(i_-\) corresponding, respectively, to one of the TLL eigenmodes with \((+)\)-chirality.

In order to see how the bulk contacts influence the two-terminal conductance of the system, we develop below the voltage drop equations, i.e., a set of equations which determine the chemical potential of the system on each side of the bulk contacts. In the presence of 1. back-scattering, 2. electron injection (ejection), the voltage drop equation reads

\[
\begin{align*}
i_+ - i_{\text{back}} &= g_+ \frac{e^2}{h} (V_L^+ - V_L^+) \\
i_- + i_{\text{back}} &= g_- \frac{e^2}{h} (V_L^- - V_R^-)
\end{align*}
\]

where \(V_L^\pm\) and \(V_R^\pm\) are the electrostatic potentials of the eigen modes on each side of the bulk contact. Using the vector notation \(\vec{i}_{\text{bulk}} = [i_+ \ i_-]\), \(\vec{V}_L = [V_L^+ \ V_L^-]\), \(\vec{V}_R = [V_R^+ \ V_R^-]\), the voltage drop equations can be rewritten in a simpler form and can be treated in a systematic way,

\[
\vec{V}_R - \vec{V}_L = \frac{\sigma_z}{ge^2/h} \vec{i}_{\text{bulk}} - \frac{i_{\text{back}}}{ge^2/h} [1 1],
\]

where \(\sigma_z = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}\). For later convenience we introduce the following decomposition of \(\vec{i}_{\text{bulk}}\):

\[
\vec{i}_{\text{bulk}} = i_{+k_F} \Omega \begin{bmatrix} 1 \\ 0 \end{bmatrix} + i_{-k_F} \Omega \begin{bmatrix} 0 \\ 1 \end{bmatrix},
\]

where the matrix \(\Omega\) was defined in Eq. (1). \(i_{+k_F}\) and \(i_{-k_F}\) are, respectively, the currents injected from the bulk contact through \(\Psi_{+k_F} \sim e^{i\sqrt{\pi}[1 0]} \Omega \begin{bmatrix} \theta_+ \\ \theta_- \end{bmatrix}\), or through \(\Psi_{-k_F} \sim e^{i\sqrt{\pi}[0 1]} \Omega \begin{bmatrix} \theta_- \\ \theta_+ \end{bmatrix}\), where \(\theta_{\pm} = \theta \mp \phi/2\) defined in terms of \(\phi = \Phi(x = 0), \theta = \Theta(x = 0)\) are the values of chiral fields at the bulk contact \((x = 0)\). Noticing that \(\begin{bmatrix} 1, 1 \end{bmatrix} \Omega = \begin{bmatrix} 1, 1 \end{bmatrix}\), one can easily check that the total bulk injected (ejected) current is indeed

\[
i_{\text{bulk}} = [1, 1] \vec{i}_{\text{bulk}} = i_{+k_F} + i_{-k_F}.
\]

The total current \(I_L, I_R\) on each side of the bulk contact is related to \(\vec{V}_L, \vec{V}_R\) via the equations: \(I_L = \frac{e^2}{h}[1, -1] \Omega \vec{V}_L = \sigma_+ \frac{e^2}{h}[1, 1] \vec{V}_L, I_R = \frac{e^2}{h}[1, -1] \Omega \vec{V}_R = \sigma_- \frac{e^2}{h}[1, -1] \vec{V}_R\). Let us first focus on

\[
I_R - I_L = \frac{e^2}{h} \begin{bmatrix} 1, 1 \end{bmatrix} \left( \frac{\sigma_+}{ge^2/h} \frac{i_{\text{back}}}{ge^2/h} \begin{bmatrix} 1 \\ 1 \end{bmatrix} \right) = \vec{i}_{\text{back}},
\]

where we have used (3). The physical meaning of this simplest equation is far from uninteresting.

1. The total current is conserved on each side of the bulk contact, i.e., \(i_{\text{back}}\) does not appear in \(I_L - I_R\), reflecting the fact that the back-scattering conserves the total charge.
2. Even though an electron injected from the bulk contact (normal lead) splits into two fractional excitations propagating in the opposite directions, leading to \( i_+ - i_- = i_{\text{bulk}} = g (i_{+\text{kp}} - i_{-\text{kp}}) \) (see Eq. (1)), the total current added by \( i_{\text{bulk}} \) is \( i_{\text{bulk}} \) independently of \( g \).

Now we connect both ends of the sample to the reservoirs through either of the two boundary conditions discussed in section III.

A. One bulk contact with end contacts in equilibrium with bare electrons

Let us first consider the case where the sample is connected to the reservoirs via the boundary condition (3). Using the voltage drop equation (3), the boundary condition (3) at the end contacts can be written as

\[
V_S = [1 \ 0] \ \Omega \ \vec{V}_L \\
V_D = [0 \ 1] \ \Omega \ \vec{V}_R
\]

Hence

\[
V_S - V_D = V_L^T \Omega \begin{bmatrix}
1 & 1 \\
-1 & -1
\end{bmatrix} \Omega \begin{bmatrix}
\sigma \vec{V}_{\text{bulk}} \\
\sigma \vec{V}_{\text{bulk}}
\end{bmatrix}^{-1} \begin{bmatrix}
1 & 1 \\
-1 & -1
\end{bmatrix} \Omega \begin{bmatrix}
1 & 1 \\
0 & 1
\end{bmatrix} \Omega \begin{bmatrix}
\sigma \vec{V}_{\text{bulk}} \\
\sigma \vec{V}_{\text{bulk}}
\end{bmatrix}^{-1} \begin{bmatrix}
1 & 1 \\
0 & 1
\end{bmatrix}
\]

(10)

Let us first look at (11). Recall the decomposition (3). Noticing that \( \Omega \ \sigma \ \vec{V} = g \sigma \vec{V} \) is a diagonal matrix, one can rewrite the bias voltage \( V_S - V_D \) as

\[
V_S - V_D = \frac{\hbar}{e^2} \left( I_R + \frac{1}{g} i_{\text{back}} - i_{+\text{kp}} \right)
\]

(12)

due to \( i_{-\text{kp}} \Omega \begin{bmatrix}
0 & 1
\end{bmatrix} \) in \( \vec{V}_{\text{bulk}} \) does not contribute to (12). In order to see the consequence of (12) let us first consider the case: \( i_{\text{bulk}} = 0 \), i.e., electrons are neither injected nor ejected through the bulk contact. In this case the total current in the presence of the backscattered current \( i_{\text{back}} \) is given by \( I = I_R = \frac{e^2}{\hbar} (V_S - V_D) - \frac{1}{g} i_{\text{back}} \). It is very interesting to compare it with the current in the absence of bulk contact: \( I_{\text{max}} = \frac{e^2}{\hbar} (V_S - V_D) \). The result is obviously

\[
I_{\text{max}} - I = \frac{1}{g} i_{\text{back}}.
\]

(13)

which is different from the naive expectation \( I_{\text{max}} - I = i_{\text{back}} \), by a factor \( 1/g \). In the derivation of (13) the boundary condition (3) has been treated carefully with \( V_S \) and \( V_D \) being fixed. Our result, Eq. (14), which differs from the analysis in Ref. [5], leads to an important remark on the shot-noise experiment in TLL. [26]

In order to see how the two-terminal conductance is affected by the bulk contact, we connect the bulk contact to the source (S) through an ohmic resistance \( r_S \). In this case the total current circulating in the system is \( I = I_R = [1, -1] \ \Omega \ \vec{V}_R \). Therefore Eq. (12) means

\[
I = \frac{e^2}{\hbar} (V_S - V_D) - \frac{1}{g} i_{\text{back}} + i_{+\text{kp}}.
\]

(14)

Another remark is that in the physically interesting case of small \( i_{\text{bulk}} = i_+ + i_- = i_{+\text{kp}} + i_{-\text{kp}} > 0 \), \( V = V_S - r_S i_{\text{bulk}} \) where \( r_S \) is a resistance between the source and bulk contact. This means \( V_D < V < V_S \).

When the bulk contact is connected to the drain (D), one should use (11). Thus the total current \( I = I_L = [1, -1] \ \Omega \ \vec{V}_L \) can be written as

\[
I = \frac{e^2}{\hbar} (V_S - V_D) - \frac{1}{g} i_{\text{back}} - i_{-\text{kp}}.
\]

(15)

We will be interested in the case of small \( i_{\text{bulk}} < 0 \), i.e., \( V_D < V = V_D - r_D i_{\text{bulk}} \ll V_S \).

We will see in the next section that Eqs. (4) and (13) give rise to a non-trivial physical consequence, where we apply to them the results of our fractional scaling analysis. This is not only due to the specific boundary condition which we have chosen for the moment but also related to the existence of a large stationary current. In the absence of stationary current \( i_{\text{bias}} \), i.e., when \( V_S = V_D = V_0 \), which actually implies \( V_+ = V_+ = V^{(0)} = V_0 \), the scaling behavior of \( i_{\pm\text{kp}} \) is trivial: \( i_{+\text{kp}} = i_{-\text{kp}} \sim \pm[V - V_0]^{\Delta_0} \Delta \), depending on the sign of \( V - V_0 \), where \( V \) is the electrostatic potential of the bulk contact and \( \Delta \) is the anomalous scaling dimension of a TLL electron. In the case of finite SD voltage \( V_S \neq V_D \), where \( V_+ , V_- , V^{(0)}_+ \) and \( V^{(0)}_- \) are all different, we have to look into the details of fractional decomposition and find out the scaling law as a function of \( i_{\text{bias}} \). This is done in Sec. V below.

B. One bulk contact with end contacts in equilibrium with dressed eigenmodes

Before turning to the RG analysis of bulk contacts, let us briefly look at the second boundary condition discussed in section III-B, i.e., the case where the dressed eigenmode voltages are equilibrated with those of the reservoirs: \( V_L^{(0)} = V_S , V_R^{(0)} = V_D \). The particles emitted from the left (right) reservoir are moving to the right (left) and are in equilibrium with the right (left)-moving eigenstates of the TLL. This situation may be achieved
in the SWNT in the absence of screening gate. The two-terminal conductance in the present case in the absence of bulk contacts is quantized at $G_{\text{SD}}^{(2)} = g e^2/h$. In the case of one bulk contact connected to the source (S), the voltage drop equation (14) implies instead of (13)

$$I = g e^2/h(V_S - V_D) - i_{\text{back}} + i_+,$$

(16)

where the total current $I$ is given as $I = I_R = g [1, -1] V_R$. When the bulk contact is connected to the drain (D), one finds instead

$$I = g e^2/h(V_S - V_D) - i_{\text{back}} - i_-.$$

(17)

Note that in Eqs. (16,17) the correction due to the bulk contact enters as either $i_+$ or $i_-$ in contrast to Eqs. (14,15). As a result, we will see that the leading scaling exponents which appear in Eqs. (16,17) are different from the ones in (14,15) and that they are simply related to the anomalous scaling dimension $\Delta$ of the TLL electron operator. All these issues concerning the scaling behavior of Eqs. (14,15,16,17) will be discussed in detail in the next section. However the reader who is more interested in the physical consequences of the analysis in this section than a detailed derivation of RG equations can skip to Eqs. (26,27) and Sec. V-C.

V. RG ANALYSIS FOR THE 3T CONDUCTANCE MEASUREMENT

We are mostly interested in the leading order corrections to the conductance in the presence of bulk contact under two different boundary conditions discussed in Sec. III-A and Sec. III-B. It is not difficult to realize using the standard scaling analysis that the backscattered current is IR-relevant whereas the bulk-injected current is UV-relevant for repulsive interaction ($0 < g < 1$), i.e., $i_{\text{back}}/(V_S - V_D)$ ($i_{\text{bulk}}/(V_S - V_D)$) scales to smaller (larger) values as the SD voltage $V_S - V_D$ is increased. However as we will see later in this section, more precise understanding of the scaling will become necessary in the analysis of Eqs. (14,15,16,17). In particular it turns out less trivial in a chirally separated system but essential in the discussion of conductance to identify the cutoff energy scale $\Lambda$ which defines the upper limit of physically meaningful energy scales.

In the case of standard backscattering problem without $i_{\text{bulk}}$, (22) there are two fixed points on the RG flow diagram, usually drawn in terms of the conductance $G_{\text{SD}}^{(2)}$ (y-axis) as a function of $\Lambda$ (x-axis). The two fixed points are at $G_{\text{SD}}^{(2)} = 0$ ($\Lambda = 0$) and either at $G_{\text{SD}}^{(2)} = e^2/h$ or at $G_{\text{SD}}^{(2)} = g e^2/h$ ($\Lambda \to \infty$). Here we are interested in the latter UV (ohmic) limit in the presence of $i_{\text{bulk}}$. We will see that the 3T SD conductance $G_{\text{SD}}^{(3)}$ shows an UV-relevant deviation and interpolates between the standard 2T values: $G_{\text{SD}}^{(2)} = e^2/h$ and $G_{\text{SD}}^{(2)} = g e^2/h$.

We start with the Euclidian Lagrangian density for non-chiral TLL,

$$\mathcal{L}_{\text{TLL}} = \frac{u}{2} \left[ \frac{1}{g} \left( \frac{\partial \Phi}{\partial x} \right)^2 + g \left( \frac{\partial \Theta}{\partial x} \right)^2 \right] + i \frac{\partial \Phi}{\partial \tau} \frac{\partial \Theta}{\partial \tau},$$

(18)

We do not consider for the time being the effects of end contacts. On the other hand we take into account the existence of a stationary current $I_{\text{bias}}$. In the absence of bulk contact, the TLL has two chiral eigen modes respectively at voltages $V_+$ and $V_-$. These voltages $V_+$ and $V_-$ are related to the stationary current $I_{\text{bias}}$ via $I = g e^2/h [1, -1] V_i$.

The bulk contact is at $x = 0$. All the bosonic fields involved in backscattering or tunneling should be understood as those at $x = 0$. Therefore it is convenient to integrate out the continuum degrees of freedom in (18) to obtain the effective action at $x = 0$.

$$S_0 = \frac{1}{\beta} \sum_{\omega} |\omega| \left( \frac{1}{g} |\phi(\omega)|^2 + g |\theta(\omega)|^2 \right)$$

(19)

$$= \frac{g}{2\beta} \sum_{\omega} |\omega| \left( |\theta_+ (\omega)|^2 + |\theta_- (\omega)|^2 \right),$$

(20)

where $\phi = \Phi(x = 0), \theta = \Theta(x = 0)$ and $\theta_{\pm} = \theta \mp \frac{\phi}{g}$. In the back-scattering problem, $\theta$ is free and eventually can be integrated out from the effective action, but let us for the moment keep $\theta$. We need both fields in order to treat 1. back-scattered current $i_{\text{back}}, 2.$ electron injection (ejection) $i_{\text{bulk}}$, on the same footing. We will see that (20) is the suitable way of writing $S_0$ for the latter problem.

A. Backward scattering

We first consider the backscattering problem (22). The scattering potential due to the tunneling of quasiparticle reads

$$\mathcal{L}_{\text{back}} \sim \Gamma_{\text{back}} \left[ \Psi^+_{+kF} \Psi_{-kF} + \Psi^+_{+kF} \Psi^+_{-kF} \right] \big|_{x = 0}$$

$$\sim \delta(x) \Gamma_{\text{back}} \cos(2 \sqrt{\pi} \phi),$$

(21)

i.e., $\theta$ is free and can be integrated out from the effective action. By throwing away $\theta$-part in (19); the effective action at $x = 0$ reduces to

$$S_{\text{back}}(\Lambda) = \frac{1}{\beta g} \sum_{|\omega| < \Lambda} |\omega| |\phi_\Lambda(\omega)|^2$$

$$+ \Gamma_{\text{back}}(\Lambda) \int_0^\beta d\tau \cos(2 \sqrt{\pi} \phi_\Lambda).$$

(22)

This effective theory is meaningless unless we find a suitable high-frequency cutoff $\Lambda$, i.e., starting from bare cutoff
\( \Lambda_0 \), we integrate out the high-frequency unphysical degrees of freedom down to \( \Lambda \). By decomposing the bosonic field \( \phi \) in Fourier space into fast \((\Lambda - d\Lambda < \omega < \Lambda)\) and slow \((0 < \omega < \Lambda - d\Lambda)\) parts and then integrating out the high-frequency modes \( \Lambda - d\Lambda < \omega < \Lambda \), one obtains the RG equation for \( \Gamma_{\text{back}}(\Lambda) \) as
\[
\Gamma_{\text{back}}(\Lambda_0) \left( \frac{d}{d\Lambda} \right)^{g-1}. \]
The scaling behavior of backscattered current \( i_{\text{back}} \) is deduced from the RG equation by identifying the physical \( \Lambda \) to be \( \Lambda_{\text{back}} = g e(V_+ - V_-) = V_S - V_D \) so that \( i_{\text{back}} \sim (V_S - V_D)^{2g-1} \), where we have chosen by convention as \( V_S > V_D \). Notice that in the high-frequency (ohmic) limit \((V_S - V_D \rightarrow \infty)\) the correction to the two-terminal conductance vanishes:
\[
\frac{d}{d(V_S - V_D)} \sim (V_S - V_D)^{2(g-1)} \rightarrow 0 \text{ as long as } 0 < g < 1.
\]

B. Electron injection (ejection)

For the tunneling of electron into or out of the bulk sample, we basically follow the same spirit. Through the bulk contact at \( x = 0 \) electrons can tunnel into the bulk sample which has two chirally separated eigen modes respectively at voltages \( V_+ \) and \( V_- \) from the electron reservoir at chemical potential \( eV \). An electron incident from this electron reservoir at chemical potential \( eV \) must be decomposed into two fractionally charged quasiparticles in order to be absorbed in the bulk sample. The incident Fermi liquid electron ends up in the final state with one of the two possible electronic excitations of TLL, i.e., either
\[
\Psi_{+\text{kp}} \sim e^{-i\sqrt{\pi} \left[ \begin{array}{c} 1 \\ 0 \end{array} \right] \Omega \left[ \begin{array}{c} \theta^+ \\ \theta^- \end{array} \right]} \text{ or } \Psi_{-\text{kp}} \sim e^{-i\sqrt{\pi} \left[ \begin{array}{c} 0 \\ 1 \end{array} \right] \Omega \left[ \begin{array}{c} \theta^- \\ \theta^+ \end{array} \right]},
\]
where \( \Omega \) has been defined as \( \Omega = \frac{1}{2} \left[ \begin{array}{cc} 1 + g & 1 - g \\ 1 - g & 1 + g \end{array} \right] \). The scattering potential due to an injection or ejection of electrons at \( x = 0 \) is given, respectively, for the \(+\text{kp}-\) and \(-\text{kp}-\) channel as
\[
\mathcal{L}_{+\text{kp}} = \Gamma_{+\text{kp}} \left[ \begin{array}{c} \Psi_{+\text{kp}}^\dagger \Psi_{g=1} + \Psi_{+\text{kp}} \Psi_{g=1}^\dagger \end{array} \right] \\
\sim \Gamma_{+\text{kp}} \left[ \begin{array}{c} \Psi_{g=1} \end{array} \right] e^{i\sqrt{\pi} \left( \frac{1}{2g} \theta^+ + \frac{1}{2} \theta^- \right) + (h.c.)}], \quad (23)
\]
\[
\mathcal{L}_{-\text{kp}} = \Gamma_{-\text{kp}} \left[ \begin{array}{c} \Psi_{-\text{kp}}^\dagger \Psi_{g=1} + \Psi_{-\text{kp}} \Psi_{g=1}^\dagger \end{array} \right] \\
\sim \Gamma_{-\text{kp}} \left[ \begin{array}{c} \Psi_{g=1} \end{array} \right] e^{i\sqrt{\pi} \left( \frac{1}{2g} \theta^- + \frac{1}{2} \theta^+ \right) + (h.c.)}], \quad (24)
\]
The total effective action is
\[
S_{\text{bulk}} = \frac{g}{2\beta} \left[ \sum_{|\omega|<\Lambda_+} |\omega| |\theta^+(\omega)|^2 + \sum_{|\omega|<\Lambda_-} |\omega| |\theta^-(\omega)|^2 \right] + \int_0^\beta d\tau \mathcal{L}_{+\text{kp}}[\theta^+, \theta^-] + \int_0^\beta d\tau \mathcal{L}_{-\text{kp}}[\theta^+, \theta^-], \quad (25)
\]
where we have introduced two frequency cut-offs \( \Lambda_+ \) and \( \Lambda_- \), respectively, for \( \theta^+ \) and for \( \theta^- \). Notice that in Eq. \((23)\) \( S_0 \) is represented as \((20)\). Now we derive the RG equation for \( \Gamma_{+\text{kp}}(\Lambda_+, \Lambda_-) \) and \( \Gamma_{-\text{kp}}(\Lambda_+, \Lambda_-) \) using the standard perturbative RG analysis. At leading order the two RG equations are decoupled and can be treated independently. Furthermore the cutoff frequencies \( \Lambda_+ \) and \( \Lambda_- \) can be different for the two RG equations, since available energy shells in \( S_0 \) for \((23)\) and \((24)\) can be different. The crucial step is, therefore, to find these cut-off frequencies, i.e., \( \Lambda_{+\text{KP}}, \Lambda_{-\text{KP}} \) for \( \Gamma_{+\text{KP}}, \) and \( \Lambda_{-\text{KP}} \) for \( \Gamma_{-\text{KP}} \). In the Appendix these cutoffs are derived based on a microscopic analysis where the fractionalization of an incident electron is explicit. By simply observing the physical processes in \((23)\), it is however not difficult to convince ourselves that the natural cutoffs for \((23)\) are \( \Lambda_{+\text{KP}} = \Lambda_{-\text{KP}} = e(V - V_+^0) \), where \( V_+^0 = \frac{1}{2} + i\in V_+ + \frac{1}{2} eV_- \) is the chemical potential of a \(+\text{kp}-\) electron incident from two chiral eigenmodes of TLL. Thus the RG equation for \( \Gamma_{+\text{kp}}(\Lambda) \) as \( \Gamma_{+\text{kp}}(\Lambda) = \Gamma_{+\text{kp}}(\Lambda_0) (\Lambda/\Lambda_0)^{\Delta + 1/2 - 1} \), where \( \Delta = \frac{1}{4} \left( g + \frac{1}{g} \right) \) is nothing but the anomalous scaling dimension of a TLL electron operator. The scaling behavior of bulk injected current \( i_{+\text{kp}} \) is deduced from the RG equation by identifying the physical \( \Lambda \) to be
\[
\Lambda = \Lambda_{+\text{kp}} = \Lambda_{-\text{kp}} = e(V - V_+^0) \text{ as}
\]
\[
i_{+\text{kp}} \sim \begin{cases} (V - V_+^0)^{2\Delta} & \text{ for } V > V_+^0 \\
- (V_+^0 - V)^{2\Delta} & \text{ for } V < V_+^0 \end{cases} \quad (26)
\]
Note that the energy dependence of Eq. \((26)\) is not a simple product of two chiral components such as \((V - V_+)^\Delta (V - V_-)^\Delta \) as might be naively expected. The same argument applies for the RG equation for \( \Gamma_{-\text{kp}} \). The scaling behavior of bulk injected current \( i_{-\text{kp}} \) is obtained as
\[
i_{-\text{kp}} \sim \begin{cases} (V - V_-^0)^{2\Delta} & \text{ for } V > V_-^0 \\
- (V_-^0 - V)^{2\Delta} & \text{ for } V < V_-^0 \end{cases} \quad (27)
\]
where \( eV_+^0 = \frac{1}{2} eV_+ + \frac{1}{2} eV_- \) is the chemical potential of \(-\text{kp}-\) electron. In the absence of stationary current \( I_{\text{bias}} \), both Eqs. \((26)\) and \((27)\) reduce to the trivial scaling law: \( i_{+\text{kp}} \sim i_{-\text{kp}} \sim |V - V_0|^2 \Delta \), depending on the sign of \( V - V_0 \).

C. Conductances

We now turn to the discussion of the physical consequences of Eqs. \((14)\) and Eqs. \((17)\), which correspond, respectively, to the boundary conditions discussed in Secs. III-A and III-B. In Secs V-A and V-B, in particular, in Eqs. \((26)\) and \((27)\), we were able to relate the
bulk injected currents $i_{+;k'+}^+$ to local energy scales in the vicinity of the bulk contact such as $V - V_+^{(0)}$ or $V - V_0^{(0)}$. In order to compare this term with other contributions one has to rewrite them in terms of the source-drain voltage $V_S - V_D$. We focus on the case where the two end contacts impose a large stationary current $I_{\text{bias}}$ in the quantum wire so that

1. The chiral symmetry of the system should be preserved.

2. The additional current injected through the bulk contact can be treated as a small perturbation.

We will see that under the two boundary conditions discussed in Sec. III-A and Sec. III-B, the 3T SD conductance $G_{\text{SD}}^{(3)}$ interpolates between the two fixed points: $G_{\text{SD}} = \frac{e^2}{h}$ and $G_{\text{SD}} = ge^2/h$ in the ohmic limit. We found non-trivial scaling exponents as a result of specific boundary condition and electron fractionalization.

1. One bulk contact with end contacts in equilibrium with bare electrons

In the case of equilibrium with bare electrons at the end contacts (see section III-A), i.e., in the case of $V_+^{(0)}$ in $[23]$ and $V_0^{(0)}$ in $[27]$ can be replaced, at leading order, by $V_+^{(0)} = V_S$ and $V_0^{(0)} = V_D$, respectively. Now let us consider the case of Eq. (14), in which the bulk contact is connected to the source (S) through an ohmic resistance $r_S$. We are mainly interested in the case: $V_D < V = V_S - r_S i_{\text{bulk}} < V_S$, i.e., in the case of small $i_{\text{bulk}} > 0$, since this gives the first correction to the "end-contact model". Substituting Eq. (28) into Eq. (14), one can immediately see that the contribution to the total current $I$ of the bulk injected current obeys a power law with an exponent $2\Delta$. The important result of our RG analysis, which is carefully derived in Sec. V-A and V-B as well as in the Appendix, is that this exponent appears as a power of the voltage difference $V_S - V$ and not of the source-drain voltage $V_S - V_D$.

Now we have to rewrite this energy scale $V_S - V$ in terms of $V_S - V_D$. Let us notice that $i_{+;k'+}^+ \sim -(V_S - V)^{2\Delta}$ is negative and very small when $V_D \ll V < V_S$ since $2\Delta = \frac{1}{2} \left( g + \frac{1}{2} \right) \geq 1$. On the other hand, $i_{-;k'}^-$ is $V - V_D)^{2\Delta} \sim (V_S - V_D)^{2\Delta}$ gives a positive dominant contribution to $i_{\text{bulk}}$ compensating for the negative $i_{+;k'+}$. Thus the small voltage difference $V_S - V$ which appears in the scaling of $i_{+;k'+}^+$ can be rewritten as a function of the bias voltage $V_S - V_D$ as $V_S - V \sim i_{\text{bulk}} \sim i_{-;k'}^-$ which scales $2\Delta$. In other words, $V_S - V$ itself scales with the exponent $2\Delta$ in terms of the source-drain voltage $V_S - V_D$. The combination of these two $2\Delta$s leads to an unusual scaling behavior of the conductance measured in terms of the bias voltage $V_S - V_D$:

$$G_{\text{SD}}^{(3)} = \frac{e^2}{h} - c_1(V_S - V_D)^{2(g-1)} - c_2(V_S - V_D)^{(2\Delta)^2-1},$$

where $c_1$ and $c_2$ are scale-invariant positive constants. Eq. (28) constitutes one of the main results of the paper, since it not only contains a new type of scaling behavior $(V_S - V_D)^{(2\Delta)^2-1}$ but also justifies our model as a possible way to interpolate between the two boundary conditions. Notice that $(2\Delta)^2 - 1 \geq 0$ for $0 < g \leq 1$. Eq. (28) means that even in the ohmic regime where the backscattering current $i_{\text{back}}$ scales to zero, the two-terminal conductance in the presence of the bulk contact can be decreased due to the bulk-injected current $i_{\text{bulk}}$ and interaction $(0 < g < 1)$.

In the case of the bulk contact connected to the drain (D), i.e., Eq. (13), one finds, of course, the same universal behavior as (28) as far as one focuses on the case $V_D < V < V_S$, i.e., the leading order correction to the boundary condition (3).

2. One bulk contact with end contacts in equilibrium with dressed eigenmodes

Let us now consider the second boundary condition for the end contacts: $V_S = V_S^+$, $V_D = V_D^-$, i.e., we discuss the scaling behavior of (16,17). In this case, depending on whether the bulk contact is connected to the source (S) or to the drain (D) all the $V_i$'s in Eqs. (16), (17) can be replaced either by $V = V_+$ or by $V = V_-$. Then one can, of course, replace $V_+^+$ and $V_-^-$ respectively, by $V_S$ and by $V_D$. Substituting $V = V_+$, $V = V_S$ and $V = V_D$ into Eqs. (16), (17), one finds $\Lambda_+ = \Lambda_+^+ = \frac{1}{2}(V_S - V_D)$ as well as $\Lambda_- = \Lambda_-^- = \frac{1}{2}(V_S - V_D)$. Eqs. (28), (29) may also be rewritten accordingly. Taking into account that $i_{+;k'} = \frac{1}{2}i_{+;k'} + \frac{1}{2}i_{-;k'} > 0$ in contrast to the previous case: $i_{+;k'} < 0$, the leading scaling behavior of Eq. (16) is found to be

$$G_{\text{SD}}^{(3)} = g \frac{e^2}{h} - c_1(V_S - V_D)^{2(g-1)} + c_3(V_S - V_D)^{2\Delta-1},$$

where $c_1$ and $c_3$ are scale-invariant positive constants. Comparing with (28), one can observe that in Eq. (29),

1. The existence of the bulk current increases $G_{\text{SD}}^{(3)}$, indicating that the correction indeed interpolates between the two limiting cases, i.e., from $G_{\text{SD}} = ge^2/h$ to $G_{\text{SD}} = e^2/h$.

2. The correction due to the bulk current does not scale in the same way. Note that the exponent of Eq. (29) is simply related to the anomalous scaling dimension of a TLL electron operator.
3. Remarks on energy scales

Before ending this section, we would like to make some remarks on the energy scales where Eqs. (28,29) are valid.

1. We have neglected the backscattering at the interface between the 1D sample and the reservoirs. This is justified when \( \epsilon(V_S - V_D) \gg \Lambda_{\text{end}} \), where \( \Lambda_{\text{end}} \) is a crossover energy associated with the quasiparticle-electron tunneling duality model at effective filling factor \( \nu_{\text{eff}} \).

2. In order for Eqs. (28,29) to be valid it is also required that backscattering in the bulk (at the bulk contact or due to some impurities in the bulk) can be treated perturbatively. This situation is achieved when \( \epsilon(V_S - V_D) \gg \Lambda_{\text{back}} \), where \( \Lambda_{\text{back}} \) is another crossover energy scale: \( \Lambda_{\text{back}} \propto \Gamma_{\text{back}}(\Lambda_0)^{1/(1-\eta)} \).

3. Finally \( V_S - V_D \) must be sufficiently large so that the perturbative analysis for the electron injection (ejection) can be justified, i.e., \( \epsilon(V_S - V_D) \gg \Lambda_{\text{bulk}} \), where \( \Lambda_{\text{bulk}} \propto \Gamma_{\text{bulk}}(\Lambda_0)^{2/(1-2\Delta)} \), \( \Delta = \frac{1}{4} \left( g + \frac{1}{g} \right) \).

We have also assumed that

1. the temperature \( T \) is sufficiently low,
2. the typical size \( L \) of the system is large enough,

so that \( \epsilon(V_S - V_D) \gg T, u/L \) should be satisfied, where \( u = v_F/g \) is the velocity of the chiral eigen modes.

We studied the effects of one bulk contact as a leading order correction to the two limiting cases of end contact model: (A) \( G_{\text{SD}} = e^2/h \) and (B) \( G_{\text{SD}} = ge^2/h \), corresponding, respectively, to the (A) the presence and (B) the absence of screening by a metallic gate discussed in Sec. III. We found,

1. In both cases \( G_{\text{SD}}^{(3)} \) is not quantized even in the ohmic limit \( V_S - V_D \to \infty \), interpolating between the two limiting cases: (A) \( G_{\text{SD}} = e^2/h \) and (B) \( G_{\text{SD}} = ge^2/h \).

2. The correction due to the bulk current, however, does not scale in the same way (see Eqs. (28) and (29)). In the presence of screening metallic gate, i.e., in the case of Eq. (28), it exhibits a pronounced scaling behavior: \( (V_S - V_D)^{(2\Delta)^2-1} \), where \( 2\Delta = \frac{1}{4} \left( g + \frac{1}{g} \right) > 1 \) \( (2\Delta = 1) \) for (non) interacting case.

In terms of the RG picture introduced at the beginning of this section, UV-relevant deviation from the standard two fixed points: (A) \( G_{\text{SD}} = e^2/h \) and (B) \( G_{\text{SD}} = ge^2/h \) may suggest a possibility of new continuous fixed points between the above two values.

VI. GENERALIZATION TO MANY BULK CONTACTS

In this section we continue the analysis of the bulk contacts. Some of the electrons are injected into the nanotube through \( N_L \) bulk contacts in the left reservoir (others are through the end contact). Both of them contribute to the total current \( I \) which flows through the sample. Similarly in the right reservoir some electrons are ejected from the nanotube not only at both ends but also through one of the \( N_R \) bulk contacts. In brief we generalize the analysis of one bulk contact to many bulk contacts.

This model is clearly inspired by the work of Chamon and Fradkin. The curious result derived in Ref. [25] is that the conductance is not monotonous as a function of \( N_R \) and \( N_L \) (Sec. III-C), and has a sort of damped oscillatory behaviour which depends on the parities of \( N_R \) and \( N_L \). So we were curious to determine if such a non-monotonous behaviour would also be predicted in the case of the non-chiral TLL, and if the renormalized conductance could be experimentally measured in the case of many contacts, as opposed to the situation found in [25]. As will appear below, our answer is that the non-chiral TLL does not behave like a chiral one as far as the number of contacts is concerned, although the conductance results are affected when weak contacts are applied in the bulk of the sample strongly connected to reservoir through its end points.

Another motivation behind this type of model is the experiment by Kasumov et. al. [17] where they found a clear signature of superconducting behavior in isolated SWNT samples as well as nanotube ropes. In this experiment the isolated SWNT sample \( ST_1 \) exhibits a resistance \( R \) which saturates at high temperatures to \( R \sim 25k\Omega \) (see Fig. 2B of Ref. [17]). As has been already mentioned, this corresponds to the conductance \( G_{\text{SD}} \sim e^2/h \), which is smaller by a factor 1/4 than \( G_{\text{SD}} \sim 4e^2/h \) expected from the boundary condition (3). In this experiment the nanotubes are embedded (melt) into the reservoirs at both ends. Given the finite radius of the nanotube (\( \sim 1.5\text{nm} \)) and possible roughness of the electrode surface from which the nanotube emerges, it is legitimate to question the validity of single point contact model. What is hoped here is that our model with a weak bulk contact is a first step towards a proper description of this experimental situation.

A. Many bulk contacts with end contacts in equilibrium with bare electrons

Consider \( N_R + N_L \) independent bulk contacts \( N_L \) of which are connected to the source (S) and the rest of which to the drain (D). The boundary condition (3) is generalized to
Let us focus on the nth bulk contact \((n = 1, \cdots, N_R)\), which is, by definition, connected to the drain (D). The voltage equations at nth bulk contact can be written as:
\[
i_n^+ - i_n^\text{back} = g_\text{ge}^2 n (V_{n+1} - V_n), \quad i_n^- + i_n^\text{back} = g_\text{ge}^2 (V_n - V_{n-1}).\]

Using the vector notation \(\vec{i}_n = \begin{bmatrix} i_n^+ \\ i_n^- \end{bmatrix}\), \(\vec{V}_n = \begin{bmatrix} V_{n-1} \\ V_n \end{bmatrix}\), one may rewrite the voltage drop equation as:
\[
\vec{V}_{n-1} - \vec{V}_n = \frac{\sigma_{\text{ge}}^n \vec{V}_{\text{bulk}}}{e^2 / h} - \frac{\text{back}}{e^2 / h} \begin{bmatrix} 1 \\ 1 \end{bmatrix}.
\]

The total current circulating in the system is defined as \(I = I_0 = [1, -1] \Omega \vec{V}_0\). Using recursively the voltage equation, one finds:
\[
\vec{V}_N = \vec{V}_0 + \sum_{n=1}^{N_R} \left( \frac{\sigma_{\text{ge}}^n \vec{V}_{\text{bulk}}}{e^2 / h} - \frac{\text{back}}{e^2 / h} \begin{bmatrix} 1 \\ 1 \end{bmatrix} \right).
\]

Using recursively these voltage drop equations, one finds:
\[
V_S = [1 0] \Omega \vec{V}_0 - \sum_{n=1}^{N_L} \left( \frac{\sigma_{\text{ge}}^n \vec{V}_{\text{bulk}}}{e^2 / h} - \frac{\text{back}}{e^2 / h} \begin{bmatrix} 1 \\ 1 \end{bmatrix} \right),
\]
\[
V_D = [0 1] \Omega \vec{V}_0 + \sum_{n=1}^{N_R} \left( \frac{\sigma_{\text{ge}}^n \vec{V}_{\text{bulk}}}{e^2 / h} - \frac{\text{back}}{e^2 / h} \begin{bmatrix} 1 \\ 1 \end{bmatrix} \right).
\]

Thus the bias voltage \(V_S - V_D\) can be expressed in terms of \(\vec{V}_0\), \(i_n^\text{back}\) and \(i_n^\text{bulk}\) as:
\[
V_S - V_D = [1, -1] \Omega \vec{V}_0 + \sum_{n=1}^{N_L} \frac{i_n^\text{back}}{e^2 / h} + \sum_{n=1}^{N_R} \frac{i_n^\text{back}}{e^2 / h} - [1, -1] \Omega \vec{V}_0.
\]

Recall that \(\Omega \sigma_{\text{ge}} \Omega = g \sigma_{\text{ge}}\). Using the decomposition analogous to (3), one can see that \(i_{n,k_n}^- (n = 1, \cdots, N_L)\) and \(i_{n,k_n}^+ (n = 1, \cdots, N_R)\) do not contribute to (31). The total current circulating in the system is \(I = I_0 = [1, -1] \Omega \vec{V}_0\).

B. Many bulk contacts with end contacts in equilibrium with dressed eigenmodes

In the case of equilibration with dressed eigenmodes the boundary condition (30) should be replaced by \(V_S = V_{-N_R}, V_D = V_{-N_L}\). Using the same voltage drop equations, one can easily see, using the decomposition analogous to (3), that \(i_{n}^- (n = 1, \cdots, N_L)\) and \(i_{n}^+ (n = 1, \cdots, N_R)\) do not contribute to the total current \(I = I_0 = [1, -1] \Omega \vec{V}_0\). Then the leading scaling behavior of the conductance in terms of the bias voltage reduces to (24) independently of \(N_R\) and \(N_L\).

VII. TLL WITH INTERNAL DEGREES OF FREEDOM — APPLICATION TO SWNT AND MWNT

Up to now we have considered for simplicity spinless TLL model, where \(2 \Delta = \frac{1}{h} \left( g + \frac{1}{2} \right)\). In order to apply the above results, in particular, Eqs. (23) and (24) for nanotubes let us recall the following properties of SWNT and MWNT. The SWNT have four conductance channels: two subbands \( \times \) (charge, spin) at room-temperatures, indicating an expected quantized conductance: \(G_{SD} = 4e^2/h\).

The experimental data for conductance measurements in SWNT and MWNT display a variety of results. The ballistic transport in carbon nanotubes was first observed in MWNT, showing the conductance \(G_{SD} \sim 2e^2/h\). This implies that in MWNT only one of the two subband contributes to the electronic transport. In the case of SWNT, the observed conductance exhibits fluctuations versus Fermi energy approaching to the theoretically expected value: \(G_{SD} = 4e^2/h\) as the temperature is lowered.
four TLL parameters: $g_{c+}, g_{c-}, g_{s+}, g_{s-}$. The scaling dimension $\Delta$ of TLL electron operator can be written, for example, in terms of these TLL parameters as $\Delta_{\text{SWNT}} = \frac{1}{10} \sum_f (g_f + \frac{1}{g_f})$. Whereas the charge conductance $G_{\text{SD}}$ is determined only by $g_{c+}$, i.e., $G_{\text{SD}} = 4g_{c+}e^2/h$, as was the case for TLL with spin [1]. In any case one can verify by carefully investigating the effective Coulomb interaction in SWNT [21] that the interaction gives rise to a significant renormalization only for $g_{c+}$, whereas $g_f \sim 1$ for $f = c-, s+, s-$ (neutral modes). Thus the TLL parameter $g$ for SWNT is defined as $g = g_{c+}$, which is estimated to be typically in the range $0.2 - 0.3$.

To summarize one has to make the following replacements in order to apply Eqs. (28) and (29) for SWNT:

1. The anomalous scaling dimension $\Delta$ of TLL electron operator should be replaced by $\Delta_{\text{SWNT}} = \frac{1}{10} \left( g + \frac{1}{g} \right) + \frac{2}{3}$.

2. The ohmic conductance in equilibrium either with bare electrons ($G_{\text{SD}}^{(2)} = e^2/h$) or with dressed eigenmodes ($G_{\text{SD}}^{(2)} = ge^2/h$) should be multiplied by 4, in order to account for the number of conducting channels.

Apart from these changes, however, the main claims of the preceding sections remain unchanged.

VIII. DISCUSSION AND CONCLUSIONS

In the first half of this paper we argued that in the case of standard end-contact geometry, the two-terminal conductance $G_{\text{SD}}^{(2)}$ in the ohmic limit can be either $G_{\text{SD}}^{(2)} = e^2/h$ or $G_{\text{SD}}^{(2)} = ge^2/h$ depending on the boundary conditions. In our point of view, different boundary conditions apply in the presence or absence of a metallic gate close to the 1D sample.

It is plausible that the boundary conditions studied in refs. [22, 24, 31] are realized when a gate is present close enough to the wire. This is suggested by the agreement between the result of Ref. [22] and the theoretical analysis using boundary conditions such that bare reservoir electrons are not in equilibrium with dressed eigenmode of the TLL, but with bare particles inside the TLL.

On the other hand, more recent experiments suggest that a variety of other boundary conditions are realized experimentally [22] by [17]. It is tempting to interpret the result of Kasumov et. al. [17] as a consequence of boundary conditions such that bare reservoir electrons are in equilibrium with dressed TLL eigenmodes.

The absence of a gate in this experiment suggests that long-range interactions inside the carbon nanotube are instrumental in bringing about this different boundary condition. If our analysis is correct, a check would be to measure the nanotube conductance in the presence of a metallic gate sufficiently close to the nanotube compared with the sample length for the interactions to be screened. Then we would expect $G_{\text{SD}}^{(2)} = 4e^2/h$. It is striking that the result of Kasumov et. al., if interpreted as $G_{\text{SD}} = 4ge^2/h$, where $g$ would be the TLL interaction parameter, yields a value $g \sim 0.25$ in very good agreement with the theoretical value calculated in Ref. [21].

Other experiments [12, 14] clearly suggest other boundary conditions [20].

Now the nature of two fixed points was understood as different boundary conditions at the end contacts by making clear distinction between the bare and dressed eigenmode densities in the bosonized formulation. In the second half of the paper we proposed a system of 1D sample coupled to bulk contacts as well as end contacts where we found qualitatively different behaviors of the conductance, e.g., different scaling dimensions, as a consequence of a large stationary current. As a result, we found that the addition of bulk contacts interpolates between the two fixed points. The RG analysis for this problem has been developed by taking into account explicitly the fractionalization of electronic charge.

We studied in particular the leading scaling behavior of the corrections to the two-terminal conductance $G_{\text{SD}}^{(3)}$ in the presence of bulk-injected current in (A) the presence and (B) the absence of screening by a metallic gate.

We found in both cases $G_{\text{SD}}^{(3)}$ is not quantized even in the ohmic limit $V_S - V_D \to \infty$, interpolating between the two limiting cases: (A) $G_{\text{SD}} = e^2/h$ and (B) $G_{\text{SD}} = ge^2/h$. The correction due to the bulk current, however, does not scale in the same way (see Eqs. (28) and (29)). In the case of Eq. (28), corresponding to the equilibration with bare electrons (Sec. III-A), it exhibits, as a consequence of this particular boundary condition (B) or more precisely Eq. (3)), a pronounced scaling behavior: $(V_S - V_D)^2(2\Delta)^{-1}$, where $2\Delta = \frac{1}{2} \left( g + \frac{1}{g} \right)$. The understanding of strong coupling limit for the bulk contact was left for future study. The discussion on the shot-noise spectrum under a variety of boundary conditions discussed in this paper is obviously of interest. This will be discussed in a forthcoming publication [26].

APPENDIX A: RG ANALYSIS FOR FRACTIONAL PARTICLES

We derive the RG equation for $\Gamma_{kp}(\Lambda_+, \Lambda_-$) and $\Gamma_{-kp}(\Lambda_+, \Lambda_-)$ starting from the effective action [25] with
(23,24). At leading order the two RG equations are decoupled and can be treated independently. The cutoff frequencies $\Lambda_+$ and $\Lambda_-$ can be different for the two RG equations, since available energy shells in $S_0$ for (23) and (24) can be different. The crucial step was, therefore, to find these cut-off frequencies, i.e., $\Lambda_{+kF}$, $\Lambda_{-kF}$ for $\Gamma_{+kF}$, and $\Lambda_{+kF}$, $\Lambda_{-kF}$ for $\Gamma_{-kF}$.

When an electron incident from the electron reservoir at chemical potential $eV$ tunnels into the TLL, it must be decomposed into two fractionally charged quasiparticles in order to be absorbed in the bulk sample. This final state TLL electron has either of the following energies $eV_+(0) = [1\ 0] \Omega \begin{bmatrix} eV_+ \\ eV_- \end{bmatrix}$, $eV_-(0) = [0\ 1] \Omega \begin{bmatrix} eV_+ \\ eV_- \end{bmatrix}$, respectively, for $\Gamma_{+kF}$ and for $\Gamma_{-kF}$. In contrast the energy decomposition of the incident Fermi liquid electron is quite arbitrary, i.e., $eV = [1\ 0] \Omega \begin{bmatrix} eV_+ \\ eV_- \end{bmatrix}$ for $\Gamma_{+kF}$ and $eV = [0\ 1] \Omega \begin{bmatrix} eV_+ \\ eV_- \end{bmatrix}$ for $\Gamma_{-kF}$, where $V_1$ ($V_2$) is a part of the electrostatic potential attributed to the $(+(-))$-chirality. The only constraint is that both $V_1 - V_2$ and $V_2 - V_1$ should have the same sign, i.e., they are positive (negative) when the current is injected (ejected). Taking into account this constraint, one can count the available energy shells for tunneling. These procedures are schematically explained in Fig. 3.

FIG. 3. Available energy shells for the tunneling into TLL.

Let us focus on the RG equation for $\Gamma_{+kF}$, i.e., for the tunneling of $+kF$ electron. On the left it is shown that the final state TLL electron has either of the following energies $eV_+(0) = [1\ 0] \Omega \begin{bmatrix} eV_+ \\ eV_- \end{bmatrix}$, $eV_-(0) = [0\ 1] \Omega \begin{bmatrix} eV_+ \\ eV_- \end{bmatrix}$, respectively, for $\Gamma_{+kF}$ and for $\Gamma_{-kF}$. On the right we focus on the tunneling of $+kF$ electron incident from the bulk contact at chemical potential $eV$. We consider the case $V_+(0) < V < V_+$. The energy of the incident electron is decomposed into each chirality as $eV = [1\ 0] \Omega \begin{bmatrix} eV_+ \\ eV_- \end{bmatrix}$. In order for a current to be injected, $V_+ \geq V$ must be satisfied. When $V_+ = V$, $V - V_+ = \frac{1 + g}{1 - g} (V + V_+ - V)$. Starting from this value, $V_2$ can take values down to $V_2$. When $V_2$ reaches this limit, where we redefine the energy decomposition of the incident electron as $eV = [1\ 0] \Omega \begin{bmatrix} eV''_+ \\ eV''_- \end{bmatrix}$, therefore, $V'' = V_-$, the other $V''$ satisfies $V'' - V = \frac{1 - g}{1 + g} (V - V_+)$. The cutoff energy scales which appear in the RG equation for $\Gamma_{+kF}$ are determined as $\Lambda_{+kF} = \frac{1 - g}{1 + g} eV_+(0) = \Lambda_{-kF} = \frac{1 - g}{1 + g} eV_-(0)$.

Thus we were able to derive on microscopic grounds the energy cutoffs which we have used to find (26),

$$
\Lambda_{+kF} = \frac{1 + g}{2} e \left[ \frac{1 - g}{1 + g} (V - V_-) - (V_+ - V) \right],
$$

$$
\Lambda_{-kF} = \frac{1 - g}{2} e \left[ (V - V_-) - \frac{1 + g}{1 - g} (V_+ - V) \right].
$$

(A1)

Hence the RG equation for $\Gamma_{-kF}$ takes the same form as that of $\Gamma_{+kF}$ except that one should identify $\Lambda$ to be $\Lambda_{+kF} = \Lambda_{-kF} = V - V'$.

[26] In this work we shall consider only the above two boundary conditions as far as end contacts are concerned — A more general thermodynamic approach including a prediction on the shot-noise spectrum under a variety of boundary conditions will be discussed in K.-I. Imura, K.-V. Pham, P. Lederer and F. Piéchon, in preparation.
[27] Of course, the stationary component of $\rho_\pm^{(0)}(x, t)$ corresponds to the number of bare excitations, i.e., those at $+k_F$ and at $-k_F$: $Q_\pm^{(0)} = \int_{-L/2}^{L/2} \rho_\pm^{(0)}(x, t),$ where $Q_\pm^{(0)} = \frac{1}{2} (N \pm J)$. $Q_\pm^{(0)}$ and $Q_\pm$ are related through the matrix

$$\Omega: \begin{bmatrix} Q_+ \\ Q_- \end{bmatrix} = \Omega \begin{bmatrix} Q_+^{(0)} \\ Q_-^{(0)} \end{bmatrix},$$

where $\Omega = \frac{1}{2} \begin{bmatrix} 1+g & 1-g \\ 1-g & 1+g \end{bmatrix}$.

[33] In this case the crossover from weak tunneling to ohmic regime would be worth mentioning [22]. The idea is to map the system to an equivalent quasiparticle-electron tunneling duality model [24] at effective filling factor $\nu_{eff}$. The system (=sample+reservoirs) is first modeled as a chiral electron tunneling model with different fictitious filling factors, i.e., $\nu_1 = g$ and $\nu_2 = 1$. Then a rotation in the space of bosonic field is applied. $\nu_{eff}$ is obtained by comparing the scaling dimension of electron tunneling operators in the original and rotated models: $\frac{1}{\nu_1} + \frac{1}{\nu_2} = 2 \nu_{eff}$. In the strong electron tunneling (ohmic) limit we have a boundary condition $I = \nu_{eff} \frac{\partial}{\partial x} (V_S - V_-)$. Together with a voltage drop equation: $I = \nu_{eff}^2 (V_+ - V_-)$ this amounts to the boundary condition [3].

[40] For $N_R$ ($N_L$) point-like contacts connected to the right (left) reservoir, the two-terminal conductance is given in the strong-coupling for each contact as

$$G_{SD} = \nu \frac{e^2}{h} \begin{bmatrix} 1 - \left( -\frac{1}{N_L} \right)^{N_L} \\ 1 - \left( -\frac{1}{N_R} \right)^{N_R} \end{bmatrix}.$$
