Incidental COVID-19 related lung apical findings on stroke CTA during the COVID-19 pandemic

Shingo Kihira1, Javin Schefflein, Michael Chung, Keon Mahmoudi, Brian Rigney, Bradley N Delman, J Mocco, Amish Doshi, Puneet Belani

ABSTRACT
Background Authors have noticed an increase in lung apex abnormalities on CT angiography (CTA) of the head and neck performed for stroke workup during the coronavirus disease 2019 (COVID-19) pandemic.
Objective To evaluate the incidence of these CTA findings and their relation to COVID-19 infection.
Methods In this retrospective multicenter institutional review board-approved study, assessment was made of CTA findings of code patients who had a stroke between March 16 and April 5, 2020, at six hospitals across New York City. Demographic data, comorbidities, COVID-19 status, and neurological findings were collected. Assessment of COVID-19 related lung findings on CTA was made blinded to COVID-19 status. Incidence rates of COVID-19 related apical findings were assessed in all code patients who had a stroke and in patients with a stroke confirmed by imaging.
Results The cohort consisted of a total of 118 patients with mean±SD age of 64.9±15.7 years and 57.6% (68/118) were male. Among all code patients who had a stroke, 28% (33/118) had COVID-19 related lung findings. RT-PCR was positive for COVID-19 in 93.9% (31/33) of these patients with apical CTA findings. Among patients who had a stroke confirmed by imaging, 37.5% (18/48) had COVID-19 related apical findings. RT-PCR was positive for COVID-19 in all (18/18) of these patients with apical findings.
Conclusion The incidence of COVID-19 related lung findings in stroke CTA scans was 28% in all code patients who had a stroke and 37.5% in patients with a stroke confirmed by imaging. Stroke teams should closely assess the lung apices during this COVID-19 pandemic as CTA findings may be the first indicator of COVID-19 infection.

INTRODUCTION
Coronavirus disease 2019 (COVID-19) is a clinical manifestation of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), which was first detected in Wuhan, China in December of 2019.1 COVID-19 has since spread worldwide and was declared a global pandemic on March 11, 2020.2 As of April 5, 2020, at least 122,000 confirmed cases of COVID-19 had been detected in the state of New York, with at least 7000 succumbing to COVID-19 related deaths.3 The symptoms initially reported with COVID-19 were related to pneumonia, such as cough, fever, and dyspnea. However, subsequent studies have since shown that the severity of symptoms can vary greatly, from essentially asymptomatic to life-threatening complications,4–6 with manifestations transcending the respiratory system to include gastrointestinal disease, headaches, and altered mental status.7–8

Neurologic symptoms are prevalent in COVID-19 patients, with one report9 suggesting they can be seen in approximately 36% of hospitalized COVID-19 patients. Most recently, Poyiadji et al10 reported that acute hemorrhagic necrotizing encephalopathy can be a manifestation of COVID-19 infection. The tendency of respiratory infections to increase the short-term risk of acute ischemic stroke11–18 may offer some explanation for the variety of neurological symptoms seen in this patient population. Although the exact pathway remains unestablished, it is believed that the systemic inflammatory response to the infection, rather than the microbe itself, is responsible for the elevated stroke risk. Proposed pathways include prothrombotic state, alterations in endothelial function, plaque instability, and rupture.15–18 Additionally, recent studies specific to SARS-CoV-2 have shown that the virus can cause a cytokine storm, which may induce acute ischemic strokes.19–20 CT angiography (CTA) of the neck and head that is obtained in acute workup for stroke will typically include the lung apices. With the recent alarming increase in incidence of COVID-19 infection, the authors observed abnormal findings in the apices that appeared more frequently prior to the pandemic. Recent studies showing diagnostic utility of chest CT for COVID-19,21–23 prompted the authors to investigate whether evaluation of the lung apical portions captured on CTA may have utility in affecting patient care during the COVID-19 pandemic. In this study, we aim to assess (1) what proportion of all code patients who had a stroke have lung findings on CTA, (2) what proportion of patients with confirmed stroke have lung findings on CTA, and (3) how these findings correspond to COVID-19 status diagnosed by reverse transcriptase polymerase chain reaction (RT-PCR) from nasal swabs.

METHODS
Study population
This multicenter retrospective study included patient populations of six hospitals spread across three New York City boroughs. Expedited institutional review board approval was obtained with a waiver of informed consent. Between March 16 and April 5, 2020, ‘code stroke’ was activated on a total of 141 patients presenting with acute
neurological symptoms. All ‘code stroke’ patients were included in this analysis if they underwent head and neck CTA in addition to non-contrast head CT during their acute stroke workup. Patients were excluded if they (1) did not obtain a head and neck CTA scan such as for medical contraindication (n=20) or (2) did not have sufficient clinical data in our electronic medical record system (n=3).

Scanning parameters
Standard emergent stroke protocol was performed on a 64-slice LightSpeed VCT scanner (General Electric GE Healthcare, Waukesha, Wisconsin, USA) with helical rotation time of 400 ms and tube current of 200–600 mA. Scanning was timed to acquire a 0.625 mm axial slice thickness with field of view from the level of the aortic arch to the vertex based on the initial scout radiograph. An 80 kV tube voltage was used for all patients with matrix of 512 and with a pitch of 0.5. Angiography was performed with non-ionic iodinated contrast medium (Isovue 370 mg I/mL, Optiray, Guerbet) at an injection rate of 4 mL/s. Axial and coronal maximum-intensity projection images were reconstructed from initial axial images at a slab thickness of 5.0 mm and 5.0 mm reconstruction increment for axial and coronal maximum-intensity projection images.

Data collection
Demographic characteristics, vascular risk factors, vital signs, laboratory values, and COVID-19 status were collected from our institutional electronic medical record system. Vascular risk factors included the diagnoses of hypertension, coronary artery disease, diabetes mellitus type 2, atrial fibrillation, congestive heart failure, dyslipidemia, current or former smoking status, evidence of prior stroke, and overweight/obese body mass index. COVID-19 infection was confirmed by in-house in vitro RT-PCR of nasopharyngeal swabs performed on the Roche cobas 6800/8800 systems (Roche Diagnostic, Basel, Switzerland).

Patients were considered COVID-19 negative if the RT-PCR was negative. Nasal swab was repeated typically up to three times in patients with high suspicion for COVID-19 infection if they presented with typical COVID-19 symptoms or if imaging (chest X-ray or CT chest) was incongruent with initial RT-PCR results. The presence or absence of stroke was confirmed on CT and/or MRI by a board-certified fellowship-trained neuroradiologist.

Characterization of apical lung findings on CTA
Lung apices included in each CTA field of view were evaluated for the presence or absence of ground-glass opacity (GGO) and consolidation by a board-certified and fellowship-trained cardiothoracic radiologist blinded to the COVID-19 status of the patient. Ground-glass opacity is defined as an area of increased attenuation in the lungs on CT, through which bronchial and vascular markings are preserved. Consolidation refers to more dense opacification of the lungs with obscuration of underlying vascular markings. Parenchymal findings were further characterized as either ‘typical’ (figure 1), ‘indeterminate’ (figure 2), or ‘atypical’ (figure 3) based on a recent expert consensus statement for radiology reporting of COVID-19 chest CT findings. From this consensus, ‘typical’ findings suggest high likelihood for COVID-19 infection, but because of the community prevalence, ‘indeterminate’ was also grouped as suggestive for COVID-19 in the setting of the pandemic. Thus, ‘typical/indeterminate’ findings were grouped and considered as radiologically positive for COVID-19 related findings. ‘Atypical’ was considered unlikely to be related to COVID-19 infection.

RESULTS
Clinical characteristics of patient population
Our patient cohort consisted of a total of 118 patients with mean±SD of age of 64.9±15.7 years with 57.6% (68/118) male (table 1). Of all code patients who had a stroke 40.7% (48/118) had acute infarction on imaging. Of the 118 patients, 31 (26.3%) were identified as COVID positive from nasal swab RT-PCR. The majority of patients worked up for acute stroke presented with altered mental status (35%) and dysarthria (38.1%).

Figure 1 Typical CT appearance of COVID-19 infection. Typical CT for COVID-19 pneumonia: axial CTA image of the lung apex in a patient in their 40s who presented with sudden aphasia and limb paresis and retrospectively found to have cough and fever for 1 week, shows bilateral peripheral ground-glass opacities in the left upper lobes (arrows), some with a rounded morphology in the left lung. This patient tested positive for COVID-19 on RT-PCR.

Figure 2 Indeterminate CT appearance of COVID-19 infection. Indeterminate CT for COVID-19 pneumonia: axial CTA image of the lung apex in a patient in their 50s who presented with 2 weeks of headaches, myalgias, and worsening dysarthria, shows central, perihilar ground-glass opacities in the left upper lobe (arrows). The unilateral central and unilateral distribution makes this appearance ‘indeterminate’. This patient tested positive for COVID-19 on RT-PCR.
COVID-19 related lung findings on head and neck CTA
Of all code patients who had a stroke, 28% (33/118) of patients had COVID-19 related apical lung findings (table 1). All (33/33) patients with COVID-19 related lung findings had a component of GGO. Consolidations were seen in 18.2% (6/33) of patients with COVID-19 related apical findings. Subsequent RT-PCR revealed that 26.3% (31/118) of all code patients who had a stroke tested positive for COVID-19 status, and 93.9% (31/33) of patients with COVID-19 related apical findings tested positive for COVID-19 on RT-PCR.

Among patients with confirmed stroke, 37.5% (18/48) of patients had COVID-19 related apical findings with all (18/18) apical findings having a component of GGO and only 16.7% (3/18) with consolidations. RT-PCR was positive for COVID-19 in all (18/18) these patients with COVID-related apical findings.

DISCUSSION
As the primary role of head and neck CTA during a ‘code stroke’ is to assess vascular pathology, such as a large vessel occlusion, aneurysm, or arteriovenous malformation, the lung apices may garner less attention and be regarded as having less clinical relevance. However, the authors have noticed an alarming increase in incidental findings in the apices of the lungs on CTA probably associated with an increase in COVID-19 cases during the pandemic. In this study, we demonstrated that 28% of all code patients who had a stroke and 37.5% of patients with confirmed stroke had lung apical findings on CTA related to COVID-19 and corresponding with RT-PCR findings. Thasan et al. had previously reported incidental findings in the lung apices on CTA in 20.8% of patients with confirmed strokes. In this study, we assessed only for COVID-19 related findings. The alarming rate of these lung findings draws attention to the importance of careful evaluation of the lung apices in patients who had a stroke. These findings may be the first and only indicator of a patient’s COVID-19 status during early emergency or inpatient evaluation, since standard RT-PCR from a nasal swab may take 6–12 hours or more for results. Furthermore, a patient presenting to the hospital with a suspected stroke is likely to undergo emergent CTA well before RT-PCR results are known or even performed. In addition, with low sensitivity and reliability of RT-PCR, management could be altered significantly if imaging findings suggest a positive incongruent COVID profile.

The importance of these observations to the endovascular surgeon and stroke neurologist are multifold. As these patients presented with predominantly neurologic symptoms, this studyTable 1  Demographic characteristics study population

| Variables                               | Total cohort (n=118) | Confirmed stroke* (n=48) |

*Stroke that is confirmed on imaging.
†Apical findings on CTA indicative of COVID-19 infection include typical and indeterminate findings. Note that indeterminate findings are considered secondary to COVID-19 infection during pandemic.
Neuroimaging

attests to the wide range of symptomatology associated with COVID-19 infection and raises awareness that if lung findings are observed, these patients should be placed in isolation or in a designated COVID investigation area and tested for COVID-19. If these findings are observed in the lung apices, the stroke team should wear appropriate personal protective equipment when visiting the patient. Stroke neurologists and endovascular surgeons should be aware of the significance of apical findings on CTA and consider extra precautions when evaluating these patients.

Additionally, members of the stroke team may benefit from understanding the characteristic features of COVID-19 related lung findings and differentiate them from ‘atypical’ findings as lung findings for COVID-19 may be diverse.24 In this study, we characterized the appearance of COVID-19 related findings and demonstrated that these predominantly include GGOs. Although characterization the appearance of COVID-19 related findings and

tion21 23 28 and has a sensitivity of up to 93%,21 the utility of apical evaluation on neck CTA has not been previously evaluated. Recent studies have shown that the presence of GGOs in the periphery of COVID-19.21 27 30  Furthermore, we acknowledge that chest infection and raises awareness that if lung findings are attests to the wide range of symptomatology associated with COVID-19 in patients with chest imaging manifestations outside the lung apices. Ongoing efforts to improve early COVID-19 diagnosis and patient care may benefit from extending head/neck CTA protocol during code strokes to capture the entire chest during the COVID-19 pandemic.
