Abstract

As NLP models achieved state-of-the-art performances over benchmarks and gained wide applications, it has been increasingly important to ensure the safe deployment of these models in the real world, e.g., making sure the models are robust against unseen or challenging scenarios. Despite robustness being an increasingly studied topic, it has been separately explored in applications like vision and NLP, with various definitions, evaluation and mitigation strategies in multiple lines of research. In this paper, we aim to provide a unifying survey of how to define, measure and improve robustness in NLP. We first connect multiple definitions of robustness, then unify various lines of work on identifying robustness failures and evaluating models’ robustness. Correspondingly, we present mitigation strategies that are data-driven, model-driven, and inductive-prior-based, with a more systematic view of how to effectively improve robustness in NLP models. Finally, we conclude by outlining open challenges and future directions to motivate further research in this area.

1 Introduction

NLP models, especially with the recent advances of large pretrained language models have achieved great progress and gained wide applications in the real world. Despite the performance gains, NLP models are still fragile and brittle to out-of-domain data (Hendrycks et al., 2020; Wang et al., 2019d), adversarial attacks (McCoy et al., 2019; Jia and Liang, 2017; Jin et al., 2020), or small perturbation to the input (Ebrahimi et al., 2017; Belinkov and Bisk, 2018). Those failures could hinder the safe deployment of these models in the real world, and impact NLP models’ trustworthiness to users. As a result, an increasing line of work has been conducted to understand robustness issues in the language technologies communities. Still, diverse sets of research across multiple dimensions and numerous levels of depth exist and are scattered across various communities; for instance, using a variety of definitions on a wide range of very different NLP tasks. In this work, we provide a unifying overview of what is robustness in NLP, how to identify robustness failures and evaluate model’s robustness, and systematic ways to improve robustness, as well as a conceptual schema categorizing ongoing research directions. We identify gaps between the to-date robustness work, the technical opportunities, and discuss possible paths forward.

2 Definitions of Robustness in NLP

Robustness, despite its specific definitions in various lines of research, can typically be unified as follows: denote the input as $x$, and its associated gold label for the main task as $y$, assume a model $f$ is trained on $(x, y) \sim \mathcal{D}$ and its prediction over $x$ as $f(x)$; now given test data $(x', y') \sim \mathcal{D}' \neq \mathcal{D}$, we can measure a model’s robustness by its performance on $\mathcal{D}'$, e.g., using the model’s robust accuracy (Tsipras et al., 2019; Yang et al., 2020), defined as $\mathbb{E}_{(x', y') \sim \mathcal{D}'}[f(x') = y']$. Existing literature on robustness in NLP can be roughly categorized by how $\mathcal{D}'$ is constructed: by synthetically perturbing the input (Section 2.1), or $\mathcal{D}'$ is naturally occurring with a distribution shift (Section 2.2).

2.1 Robustness against Adversarial Attacks

In one line of research, $\mathcal{D}'$ is constructed by perturbations around input $x$ to form $x'$ ($x'$ typically being defined within some proximity of $x$). This topic has been widely explored in computer vision under the concept of adversarial robustness, which measures models’ performances against carefully crafted noises generated deliberately to deceive the model to predict wrongly, pioneered by (Szegedy et al., 2013; Goodfellow et al., 2015), and later extended to NLP, such as (Ebrahimi et al., 2017; Alzantot et al., 2018; Li et al., 2018b; Feng et al., 2018; Kuleshov et al., 2018; Jia et al., 2019; Zang...
The generation of adversarial examples primarily builds upon the observation that we can generate samples that are meaningful to human (e.g., by perturbing the samples with changes that are imperceptible to human) while altering the prediction of the models for this sample. In this regard, human’s remarkable ability in understanding a large set of synonyms (Li et al., 2020) or interesting characteristics in ignoring the exact order of letters (Wang et al., 2020b) are often opportunities to create adversarial examples. A related line of work such as data-poisoning (Wallace et al., 2021) and weight-poisoning (Kurita et al., 2020) exposes NLP models’ vulnerability against attacks during the training process. One can refer to more comprehensive reviews and broader discussion on this topic in Zhang et al. (2020b) and Morris et al. (2020b).

Assumptions around Label-preserving and Semantic-preserving Most existing work in vision makes a relatively simplified assumption that the gold label of $x'$ remains unchanged under a bounded perturbation over $x$, i.e., $y' = y$, and a model’s robust behaviour should be $f(x') = f(x)$ (Szegedy et al., 2013; Goodfellow et al., 2015). A similar line of work in NLP follows the same label-preserving assumption with small text perturbations like token and character swapping (Alzantot et al., 2018; Jin et al., 2020; Ren et al., 2019; Ebrahimi et al., 2017), paraphrasing (Iyyer et al., 2018; Gan and Ng, 2019), semantically equivalent adversarial rules (Ribeiro et al., 2018), and adding distractors (Jia and Liang, 2017). However, this label-preserving assumption might not always hold, e.g., Wang et al. (2021b) studied several existing text perturbation techniques and found that a significant portion of perturbed examples are not label-preserving (despite their label-preserving assumptions), or the resulting labels have a high disagreement among human raters (i.e., can even fool humans). Morris et al. (2020a) also call for more attention to the validity of perturbed examples for a more accurate robustness evaluation.

Another line of work aims to perturb the input $x$ to $x'$ in small but meaningful ways that explicitly change the gold label, i.e., $y' \neq y$, under which case the robust behaviour of a model should be $f(x') \neq y$ (Gardner et al., 2020; Kaushik et al., 2019; Schlegel et al., 2021). We believe these two lines of work are complementary to each other, and both should be explored in future research to measure models’ robustness more comprehensively.

One alternative notion is whether the perturbation from $x$ to $x'$ is “semantic-preserving” (Alzantot et al., 2018; Jin et al., 2020; Ren et al., 2019) or “semantic-modifying” (Shi and Huang, 2020; Jia and Liang, 2017). Note this is slightly different from the above label-preserving assumptions, as it is defined over the perturbations on $(x, x')$ rather than making an assumption on $(y, y')$, e.g., semantic-modifying perturbations can be either label-preserving (Jia and Liang, 2017; Shi and Huang, 2020) or label-changing (Gardner et al., 2020; Kaushik et al., 2019).

2.2 Robustness under Distribution Shift

Another line of research focuses on $(x', y')$ drawn from a different distribution that is naturally-occurring (Hendrycks et al., 2021), where robustness can be defined around model’s performance under distribution shift. Different from work on domain adaptation (Patel et al., 2015; Wilson and Cook, 2020) and transfer learning (Pan and Yang, 2010), existing definitions of robustness are closer to the concept of domain generalization (Muan-det et al., 2013; Gulrajani and Lopez-Paz, 2021), or out-of-distribution generalization to unforeseen distribution shifts (Hendrycks et al., 2020), where the test data (either labeled or unlabeled) is assumed not available during training (generalization without adaptation). In the context of NLP, robustness to natural distribution shifts can also mean models’ performance should not degrade due to the differences in grammar errors, dialects, speakers, languages (Craig and Washington, 2002; Blodgett et al., 2016; Demszky et al., 2021), or newly collected datasets for the same task but in different domains (Miller et al., 2020a). Another closely connected line of research is fairness, which has been studied in various NLP applications, see (Sun et al., 2019) for a more in-depth survey in this area. For example, gendered stereotypes or biases have been observed in NLP tasks including co-reference resolution (Zhao et al., 2018a; Rudinger et al., 2017), occupation classification (De-Arteaga et al., 2019), and neural machine translation (Prates et al., 2019; Font and Costa-jussà, 2019).

2.3 Connections and A Common Theme

The above two categories of robustness can be unified under the same framework, i.e., whether $D'$
represents a synthetic distribution shift (via adversarial attacks) or a natural distribution shift. Existing work has shown a model’s performance might degrade substantially in both cases, but the transferability of the two categories are relatively under-explored. In the vision domain, Taori et al. (2020) investigate model’s robustness to natural distribution shift, and show that robustness to synthetic distribution shift might offer little to no robustness improvement under natural distribution shift. There are studies showing NLP models might not be able to generalize to unseen adversarial patterns (Huang et al., 2020; Jha et al., 2020; Joshi and He, 2021), but more work is needed to systematically bridge the gap between NLP model’s robustness under natural and synthetic distribution shifts.

To better understand why models exhibit a lack of robustness, some existing work attributed this to the fact that models sometimes utilize spurious correlations between input features and labels, rather than the genuine ones, where spurious features are commonly defined as features that do not causally affect a task’s label (Srivastava et al., 2020; Wang and Culotta, 2020b): they correlate with task labels but fail to transfer to more challenging test conditions or out-of-distribution data (Geirhos et al., 2020). Some other work defined it as “prediction rules that work for the majority examples but do not hold in general” (Tu et al., 2020a). Such spurious correlations are sometimes referred as dataset bias (Clark et al., 2019; He et al., 2019), annotation artifacts (Gururangan et al., 2018), or group shift (Oren et al., 2019) in the literature. Further, evidence showed that controlling model’s learning in spurious features will improve model’s performances in distribution shifts (Wang et al., 2019a,b); also, discussions on the connections between adversarial robustness and learning of spurious features has been raised (Ilyas et al., 2019; Wang et al., 2020a). Theoretical discussions connecting these fields have also been offered by crediting a reason of model’s lack of robustness in either distribution shift or adversarial attack to model’s learning of spurious features (Wang et al., 2021c).

Further, in certain applications, model “robustness” can also be connected with models’ instability (Milani Fard et al., 2016), or models having poorly-calibrated uncertainty estimation (Guo et al., 2017), where Bayesian methods (Graves, 2011; Blundell et al., 2015), dropout-based (Gal and Ghahramani, 2016; Kingma et al., 2015) and ensemble-based approaches (Lakshminarayanan et al., 2017) have been proposed to improve models’ uncertainty estimation. Recently, Ovadia et al. (2019) have shown models’ uncertainty estimation can degrade significantly under distributional shift, and call for more work to ensure a model “knows when it doesn’t know” by giving lower uncertainty estimates over out-of-distribution data. This again emphasizes the need of building more unified benchmarks to measure a model’s performance under distribution shifts, in addition to in-distribution accuracy.

3 Robustness in Vision vs. in NLP

Despite the widely study of robustness in vision, the study of robustness in NLP cannot always directly borrow the ideas. We categorize the main differences with the three following points:

Continuous vs. Discrete in Search Space The most obvious characteristic is probably the discrete nature of the space of text. This particularly posted a challenge towards the adversarial attack and defense regime when the study in vision is transferred to NLP (Lei et al., 2019; Zhang et al., 2020b), in the sense that simple gradient based method will not be efficient enough, and multiple novel attack methods are proposed to fill the gap, as we will discuss in later sections.

Perceptible to Human vs. Not On a related topic, one of the most impressive property of adversarial attack in vision is that small perturbation of the image data imperceptible to human are sufficient to deceive the model (Szegedy et al., 2013), while this can hardly be true for NLP attacks. Instead of being imperceptible, the adversarial attacks in NLP typically are bounded by the fact that the meaning of the sentences are not altered (despite being perceptible). Whether the meaning of the text fragment is changed or not largely depends on the human understanding of the sentence, quantified by language models (Minervini and Riedel, 2018). On the other hand, there are ways to generate samples where the changes, although being perceptible, are often ignored by human brain due to some psychological prior on how a human processes the text (Anastasopoulos et al., 2019; Wang et al., 2020b).

Support vs. Density Difference of the Data Distributions Another difference is more likely seen in the discussion of the domain adaptation of vision and NLP study. In vision study, although the
images from training distribution and test distribution can be sufficiently different, the train and test distributions mostly share the same support (the pixels are always sample from a 0-255 integer space), although the density of these distributions can be very different (photos vs. sketches). On the other hand, domain adaptation of NLP sometimes studies the regime where the supports of the data differ (e.g., the vocabularies can be significantly different in cross-lingual study (Abad et al., 2020; Zhang et al., 2020a)).

A Common Theme Despite the disparities between vision and NLP, the common theme of pushing the model to generalize from \( D \) to \( D' \) preserves. The practical difference between \( D \) and \( D' \) is more than often defined by the human’s understanding of the data, and can differ in vision and NLP as humans perceive and process images and texts in subtly different ways, which creates both opportunities for learning and barriers for direct transfer. Certain lines of research try to bridge the learning in the vision domain to the embedding space in the NLP domain, while other lines of research create more interpretable attacks in the discrete text space (see Table 1 for these two lines of work). How those two lines of research transfer to each other, or complement each other, is not fully explored and calls for additional research.

4 Identify Robustness Failures

As robustness gained increasing attention in NLP literature, various lines of work have proposed ways to identify robustness failures in NLP models. Existing works can be roughly categorized by how the failures are identified, among which a large portion of work relies on human priors and error analyses over existing NLP models (Section 4.1), and a few other lines of work adopt model-based approaches (Section 4.2). The identified robustness failure patterns are usually organized into challenging/adversarial benchmark datasets to more accurately measure an NLP model’s robustness. In Table 1, we organize commonly used perturbation types for identifying models’ robustness failures, and in Table 2 we summarize common robustness benchmarks for each NLP task.

4.1 Human Prior and Error Analyses Driven

An increasing body of work has been conducted on understanding and measuring robustness in NLP models (Tu et al., 2020b; Sagawa et al., 2020b; Geirhos et al., 2020) across various NLP tasks, e.g., NLI (McCoy et al., 2019), Question-Answering (Jia and Liang, 2017), and Neural Machine Translation (Niu et al., 2020), largely relying on human priors and error analyses.

Natural Language Inference Naik et al. (2018) sampled misclassified examples and analyzed their potential sources of errors, which are then grouped into a typology of common reasons for error. Such error types then served as the bases to construct the stress test set, to further evaluate whether NLI models have the ability to make real inferential decisions, or simply rely on sophisticated pattern matching. Gururangan et al. (2018) found that current NLI models are likely to identify the label by relying only on the hypothesis, and Poliak et al. (2018) provided similar augments that using a hypothesis-only model can outperform a set of strong baselines. Kaushik et al. (2019) asked humans to generate counterfactual NLI examples, aiming to gain a better understanding of what make a difference with counterfactual data.

Question Answering Jia and Liang (2017) proposed to generate adversarial QA examples by concatenating an adversarial distracting sentence at the end of a paragraph. Miller et al. (2020b) built four new test sets for the Stanford Question Answering Dataset (SQuAD) and found most question-answering systems fail to generalize to this new data, calling for new evaluation metrics towards natural distribution shifts.

Machine Translation Belinkov and Bisk (2018) found that character-based neural machine translation (NMT) models are brittle and easily falter when presented with noisy data, where noises (e.g., typos, misspellings, etc) are synthetically generated using possible lexical replacements. Augmenting training data with sentences containing artificially-introduced grammatical errors (Anastasopoulos et al., 2019) or with random synthetic noises (Vaibhav et al., 2019; Karpukhin et al., 2019) can make the system more robust to such spurious patterns. On the other hand, Wang et al. (2020b) showed another approach by limiting the input space of the characters so that the models will be likely to perceive the data typos and misspellings.

Connection with Dataset Biases The above identified robustness failures can sometimes be attributed to dataset biases, i.e., biases introduced dur-
Table 1: Perturbation types for identifying robustness failures and improving robustness in NLP.

| Space          | Perturbation level | Methods                                                                 |

4.2 Model-based Identification

In addition to the above human-prior and error-analysis driven approaches which are usually specific to each task, there is also a line of work identifying robustness failures that are either task-agnostic like white-box text attack methods (Ebrahimi et al., 2017; Jin et al., 2020; Alzantot et al., 2018), or even input-agnostic like universal adversarial triggers (Wallace et al., 2019a) and natural attack triggers (Song et al., 2021).

Another line of work proposes to learn an additional model to capture biases, e.g., in visual question answering, Clark et al. (2019) train a naive model to predict prototypical answers based on the question only irrespective of context; He et al. (2019); Utama et al. (2020a) propose to learn a biased model that only uses dataset-bias related features. This framework has also been used to capture unknown biases assuming that the lower capacity model learns to capture relatively shallow correlations during training (Clark et al., 2020). In addition, Wang and Culotta (2020a) aim at identifying shortcuts in models by training classifiers to better distinguish “spurious” correlations from “genuine” ones from human annotated examples.

Model-in-the-loop vs. Human-in-the-loop

As summarized in Table 1, most perturbation methods apply either model-in-the-loop or human-in-the-loop to generate challenging examples. Applying model-in-the-loop is beneficial in the sense that it increases the likelihood that the perturbed examples are challenging for SoTA models, but it might also introduce biases towards the particular model used, e.g., Swag (Zellers et al., 2018) was introduced that fools most models at the time of publishing but was soon “solved” after BERT (Devlin et al., 2019) was introduced. As a result, Yuan et al. (2021) present a study over the transferability of dataset collection (Fouhey et al., 2018) or human annotation artifacts (Gururangan et al., 2018; Geva et al., 2019; Rudinger et al., 2017), which could affect how well a model trained from this dataset generalizes, and how accurately we estimate a model’s performance. For example, Lewis et al. (2021) show there is a significant test-train data overlap in a set of open-domain question-answering benchmarks, and many QA models perform substantially worse on questions that cannot be memorized from training data. In natural language inference, McCoy et al. (2019) show that commonly used crowdsourced datasets for training NLI models might make certain syntactic heuristics more easily adopted by statistical learners. Further Bras et al. (2020) propose to use a lightweight adversarial filtering approach to filter dataset biases, which is approximated using each instance’s predictability score.

As summarized in Table 1, most perturbation methods apply either model-in-the-loop or human-in-the-loop to generate challenging examples. Applying model-in-the-loop is beneficial in the sense that it increases the likelihood that the perturbed examples are challenging for SoTA models, but it might also introduce biases towards the particular model used, e.g., Swag (Zellers et al., 2018) was introduced that fools most models at the time of publishing but was soon “solved” after BERT (Devlin et al., 2019) was introduced. As a result, Yuan et al. (2021) present a study over the transferability of dataset collection (Fouhey et al., 2018) or human annotation artifacts (Gururangan et al., 2018; Geva et al., 2019; Rudinger et al., 2017), which could affect how well a model trained from this dataset generalizes, and how accurately we estimate a model’s performance. For example, Lewis et al. (2021) show there is a significant test-train data overlap in a set of open-domain question-answering benchmarks, and many QA models perform substantially worse on questions that cannot be memorized from training data. In natural language inference, McCoy et al. (2019) show that commonly used crowdsourced datasets for training NLI models might make certain syntactic heuristics more easily adopted by statistical learners. Further Bras et al. (2020) propose to use a lightweight adversarial filtering approach to filter dataset biases, which is approximated using each instance’s predictability score.

4.2 Model-based Identification

In addition to the above human-prior and error-analysis driven approaches which are usually specific to each task, there is also a line of work identifying robustness failures that are either task-agnostic like white-box text attack methods (Ebrahimi et al., 2017; Jin et al., 2020; Alzantot et al., 2018), or even input-agnostic like universal adversarial triggers (Wallace et al., 2019a) and natural attack triggers (Song et al., 2021).

Another line of work proposes to learn an additional model to capture biases, e.g., in visual question answering, Clark et al. (2019) train a naive model to predict prototypical answers based on the question only irrespective of context; He et al. (2019); Utama et al. (2020a) propose to learn a biased model that only uses dataset-bias related features. This framework has also been used to capture unknown biases assuming that the lower capacity model learns to capture relatively shallow correlations during training (Clark et al., 2020). In addition, Wang and Culotta (2020a) aim at identifying shortcuts in models by training classifiers to better distinguish “spurious” correlations from “genuine” ones from human annotated examples.
of adversarial examples; Contrast Sets (Gardner et al., 2020) intentionally avoid using model-in-the-loop, and Wallace et al. (2019b); Bartolo et al. (2020); Nie et al. (2020); Kiela et al. (2021) adopt adversarial human-and-model-in-the-loop to create more difficult examples for benchmarking.

5 Improve Model Robustness

Correspondingly, there are also multiple lines of work that try to improve robustness in NLP models. Depending on where and how the intervention is applied, those approaches can be categorized into data-driven (Section 5.1), model and training-scheme based (Section 5.2), inductive-prior based and finally causal intervention (Section 5.4).

5.1 Data-driven Approaches

Data augmentation has recently gained a lot of interest, both in improving performance in low-resource language settings, few-shot learning, mitigating biases and improving robustness in NLP models (Feng et al., 2021). Techniques like Mixup (Zhang et al., 2017), MixText (Chen et al., 2020), CutOut (DeVries and Taylor, 2017), AugMix (Hendrycks et al., 2019), HiddenCut (Chen et al., 2021), have been shown to substantially improve the robustness and the generalization of models. Such mitigation strategies are operated at the data level, and often hard to be interpreted in terms of how and why mitigation works.

Other line of work deals with spans or regions associated within data points to prevent models from heavily relying on spurious patterns. To make NLP models more robust on sentiment analysis and NLI tasks, Kaushik et al. (2019) proposed curating counterfactually augmented data via a human-in-the-loop process, and showed that models trained on the combination of these augmented data and original data are less sensitive to spurious patterns. Differently, Wang et al. (2021d) performed strategic data augmentation to perturb the set of “shortcuts” that are automatically identified, and found that mitigating these leads to more robust models in multiple NLP tasks. This line of mitigation strategies closely relate to how spurious correlations can be measured and identified, as many of the challenging or adversarial examples (Table 1) can sometimes be used to augment the original model to improve its robustness, either in the discrete input space as additional training examples (Liu et al., 2019; Kaushik et al., 2019; Anastasopoulos et al., 2019; Vaibhav et al., 2019; Khashabi et al., 2020), or in the embedding space (Zhu et al., 2020; Zhao et al., 2018b; Miyato et al., 2017; Liu et al., 2020).

5.2 Model and Training Based Approaches

Pre-training Recent work has demonstrated pre-training as an effective way to improve NLP model’s out-of-distribution robustness (Hendrycks et al., 2020; Tu et al., 2020a), potentially due to its self-supervised objective and the use of large amounts of diverse pre-training data that encourages generalization from a small number of examples that counter the spurious correlations. Tu et al. (2020a) show a few other factors that can also contribute to robust accuracy, including larger model size, more fine-tuning data, and longer fine-tuning. A similar observation is made in Taori et al. (2020) in the vision domain, where the authors found training with larger and more diverse datasets offer better robustness consistently in multiple cases, compared to various robustness interventions proposed in the existing literature.

Training with a better use of minority examples Further there are several works that propose to robustify the models via a better use of minority examples, e.g., examples that are under-represented in the training distribution, or examples that are harder to learn. For example, Yaghoobzadeh et al. (2021) proposed to first fine-tune the model on the full data, and then on minority examples only.

In general, the training strategy with a emphasis on a subset of samples that are particularly hard for the model to learn is sometimes also referred to as group DRO (Sagawa et al., 2020a), as an extension of vanilla distributional robust optimization (DRO) (Ben-Tal et al., 2013; Duchi et al., 2021), which is syntactically the same as adversarial training mentioned in the data driven approaches.

Extensions of DRO are mostly discussing the strategies on how to identify the samples considered as minority. For example, Nam et al. (2020) train another model by emphasizing the model’s early-stage decisions; Lahoti et al. (2020) also use another model to identify the samples that are challenging to the main model; Liu et al. (2021) propose to train the model a second time via up-weighting minority examples that have high training loss during the first time.

When to use data-driven or model-based approaches? In many cases both the data and the model can contribute to a model’s lack of ro-
A thorough approach to understanding and mitigating errors in domain adaptation is through the use of cautionary analyses. Srivastava et al. (2020) leverage humans’ common sense knowledge of causality to augment training examples with a potential unmeasured variable, and propose a DRO-based approach to encourage the model to be robust to distribution shifts over the unmeasured variables. Balashankar et al. (2021) study the effect of secondary attributes, or confounders, and propose context-aware counterfactuals that take into account the impact of secondary attributes to improve model’s robustness. Veitch et al. (2021) propose to learn approximately counterfactual invariant predictors dependent on causal structures of the data, and show it can help mitigate spurious correlations on text classification.

5.4 Causal Intervention

Causal analyses have also been utilized to examine robustness. Srivastava et al. (2020) leverage humans’ common sense knowledge of causality to augment training examples with a potential unmeasured variable, and propose a DRO-based approach to encourage the model to be robust to distribution shifts over the unmeasured variables. Balashankar et al. (2021) study the effect of secondary attributes, or confounders, and propose context-aware counterfactuals that take into account the impact of secondary attributes to improve model’s robustness. Veitch et al. (2021) propose to learn approximately counterfactual invariant predictors dependent on causal structures of the data, and show it can help mitigate spurious correlations on text classification.

5.5 Connections of Mitigation

Connecting these methods conceptually, we conjecture three different mainstream approaches: one is to leverage the large amount of data by taking advantages of pretrained models, another is to learn invariant representations or predictors across domains/environments, while most of the rest build through the use of cautionary analyses. Srivastava et al. (2020) leverage humans’ common sense knowledge of causality to augment training examples with a potential unmeasured variable, and propose a DRO-based approach to encourage the model to be robust to distribution shifts over the unmeasured variables. Balashankar et al. (2021) study the effect of secondary attributes, or confounders, and propose context-aware counterfactuals that take into account the impact of secondary attributes to improve model’s robustness. Veitch et al. (2021) propose to learn approximately counterfactual invariant predictors dependent on causal structures of the data, and show it can help mitigate spurious correlations on text classification.
upon the prior on what the spurious/bias patterns of the data are. Then the solutions are invented through countering model’s learning of these patterns by either data augmentation, reweighting (the minorities), ensemble, inductive-prior design, and causal intervention. Interestingly, statistical work has shown that many of these mitigation methods are optimizing the same robust machine learning generalization error bound (Wang et al., 2021c).

6 Open Questions

Identifying Unknown Robustness Failures Existing identification around robustness failures rely heavily on human priors and error analyses, which usually pre-define a small or limited set of patterns that the model could be vulnerable to. This requires extensive amount of expertise and efforts, and might still suffer from human or subjective biases in the end. How to proactively discover and identify models’ unrobust regions automatically and comprehensively remains challenging. As a counterpoint, a prior-knowledge-free statistical driven identification of spurious features may not be possible (Wang et al., 2021c).

Interpreting and Mitigating Spurious Correlations Interpretability matters for large NLP models, especially key to the robustness and spurious patterns. How can we develop ways to attribute or interpret these vulnerable portions of NLP models and communicate these robustness failures with designers, practitioners, and users? In addition, recent work (Wallace et al., 2019c; Wang et al., 2021d; Zhang et al., 2021) show interpretability methods can be utilized to better understand how a model makes its decision, which in turn can be used to uncover models’ bias, diagnose errors, and discover spurious correlations.

Furthermore, the mitigation of spurious correlations often suffers from the trade-off between removing shortcut and sacrificing model performance. Additionally, most existing mitigation strategies work in a pipeline fashion where defining and detecting spurious correlations are prerequisites, which might could lead to error cascades in this process. How to design end-to-end frameworks for automatic mitigation deserves much attention.

Unified Framework to Evaluate Robustness With a variety of potential spurious patterns in NLP models, it becomes increasingly challenging for developers and practitioners to quickly evaluate the robustness and quality of their models. This calls for more unified benchmarking efforts such as Robustness Gym (Goel et al., 2021) and Dynabench (Kiela et al., 2021), to facilitate fast and easy evaluation of robustness.

User Centered Measures and Mitigation Instead of passively detecting spurious correlations from a post-processing perspective, how to approach robustness from a user centric perspective needs further investigation. Based on the dual-process models of information processing, humans use two different processing styles (Evans, 2010). One is a quick and automatic style that relies on well-learned information and heuristic cues. The other is a qualitatively different style that is slower, more deliberative, and relies on rules and symbolic logic. Would these well-learned information and heuristic rules be leveraged to help design better human priors to measure and mitigate spurious correlations? If users or stakeholders are involved in this process, collecting a set of test cases where a system might perform well for the wrong reasons could help design sanity tests.

Connection between Human-like Linguistic Generalization and NLP Generalization Linzen (2020) argue NLP models should behave more like humans to achieve better generalization consistently. It is interesting to note that how humans solve NLP tasks exactly is still under exploration, and to what extent models should leverage human-knowledge is still a debatable topic1. Nonetheless, if certain stable properties from human perception can be better understood and utilized (Geirhos et al., 2019; Hinton, 2021), it can potentially advance models’ robustness in a more meaningful way.

7 Conclusion

In this paper, we provided a comprehensive overview over robustness definitions, evaluations and mitigation strategies in the NLP domain. We highlight open challenges in this area to motivate future research, encouraging people to think deeply about more comprehensive benchmarks, transferability and validity of adversarial examples, unified framework to evaluate and improve robustness, user-centered measures and mitigation, and finally how to potentially achieve human-like linguistic generalization more meaningfully.
