(Dated: 8 December 2017)

With the rapid increase of available data for complex systems, there is great interest in the extraction of physically relevant information from massive datasets. Recently, a framework called Sparse Identification of Nonlinear Dynamics (SINDy) has been introduced to identify the governing equations of dynamical systems from simulation data. In this study, we extend SINDy to stochastic dynamical systems, which are frequently used to model biophysical processes. We prove the asymptotic correctness of stochastic SINDy in the infinite data limit, both in the original and projected variables. We discuss algorithms to solve the sparse regression problem arising from the practical implementation of SINDy, and show that cross validation is an essential tool to determine the right level of sparsity. We demonstrate the proposed methodology on two test systems, namely, the diffusion in a one-dimensional potential, and the projected dynamics of a two-dimensional diffusion process.
I. INTRODUCTION

The last decade has seen a dramatic increase in our ability to collect or produce large amounts of high resolution and high dimensional data associated with complex physical and chemical systems, both by means of experimental measurements or computer simulations. In many different scientific fields, ranging from high energy physics to neuroscience, the “big-data” problem has spurred interest in data analysis methods that can condense massive datasets into a minimal amount of essential information and/or can detect relevant patterns and anomalies in the distribution of the data.

In the specific case of molecular systems, a large body of work has been devoted to define collective coordinates and reaction pathways from molecular dynamics simulation data\textsuperscript{1,2}. However, most of the proposed techniques are descriptive and do not provide a functional link relating the variables to the observed behavior. Mathematical approaches that have been proved optimal to reduce the complexity of the data by dimensionality reduction and/or coarse graining (in time or space) usually do not offer a straightforward physical interpretation of the results. Here we take a different approach and make a first step towards the definition of methods to learn the functional form of a molecular model from the available data.

Assuming an extensive sampling of a given set of variables describing a system is available for a certain time frame, different data-driven methods have been proposed to “learn” how to propagate the system to future times, either in terms of the original variables or in a reduced representation. For instance, the so-called “equation-free” approach, uses local (in time and space) microscopic simulations to propagate macroscopic variables to long timescales\textsuperscript{3}. Such an approach bypasses the need of formulating constitutive equations for the time evolution of the macroscopic variables of the system in closed form and provides a practical recipe for multiscale simulation. However, it is oftentimes desirable to obtain an explicit analytical expression for the dynamical equations in terms of the variables of interest, as they can offer a physicochemical understanding of the system. Ideally, one would like to design approaches that are able to infer such equations from the available data. Recently, a significant step in this direction has been proposed for deterministic dynamical systems\textsuperscript{4}. The Sparse Identification of Nonlinear Dynamics (SINDy) approach combines ideas from sparse regression\textsuperscript{5,6} and compressed sensing\textsuperscript{7,8} to automatically discover
the terms of the differential equations (either ordinary\textsuperscript{4} or partial\textsuperscript{39}) that best represent large sets of time-dependent data, given a suitable function library (as it will be discussed below). For instance, it was shown that SINDy can be used to obtain the correct equation for the low-dimensional slow attractor associated with the dynamics of a fluid flow past a cylinder, that is described by the Navier-Stokes equations at the microscopic scale\textsuperscript{4}.

Such a methodology appears very promising to learn effective equations of motion in different fields of application, such as molecular systems. A significant difference that limits the application of SINDy to (macro)molecular systems is the presence of noise, as their dynamics are usually non-deterministic. Towards this goal, here we present an extension of this approach that allows to derive stochastic dynamical equations from data, either to describe the time evolution of microscopic variables or of their transformation in a different space. For the latter, we combine the SINDy idea with the formalism of projected stochastic dynamics\textsuperscript{10,11}. We show that extensive cross-validation is a crucial ingredient that needs to be added in the sparsification of the solution for this approach to be successful in the presence of significant noise and/or limited data.

The manuscript is organized as follows. First, the proposed extension of SINDy to stochastic systems and its theoretical underpinnings are outlined. We show how trajectory data can be used as an input to formulate a regression problem approximating the drift and diffusion coefficients of an Ito process, both in the microscopic and in an effective variable space. The specific algorithm used to solve the regression is then detailed, by introducing a cross validation based Stepwise Sparse Regression. Such a formalism is employed to learn dynamical equations from data for two test systems: the homogeneous diffusion in a one dimensional double well potential, and the projected dynamics along a projected coordinate in a two dimensional potential. Results and implications are finally discussed.

II. THEORY

A. Sparse Identification of Dynamical Systems

We start by outlining the SINDy approach for deterministic dynamical systems, that was originally proposed in ref.\textsuperscript{4}. The goal is to learn the dynamical equations for a system described by an ordinary differential equation:
\[
\frac{d}{dt}X(t) = F(X(t)),
\]

where \(X(t) \in \mathbb{R}^d\) is the state of the system at time \(t\) and \(F : \mathbb{R}^d \to \mathbb{R}^d\) is the vector field defining the dynamics. For many complex systems, no closed-form expression for the vector field \(F\) is known, and the process can only be observed through simulation or measurement data \(X(t_l)\), \(l = 1, \ldots, N\), where \(t_1 < \ldots < t_N\) are discrete points in time. However, it was suggested in ref. [4] to learn the dynamical equation as a linear combination of a pre-selected dictionary of basis functions. More precisely, let \(\Theta_K = (f_1, \ldots, f_K)\) be a set of \(K\) user-defined trial functions. Making the ansatz:

\[
F_i = \sum_{k=1}^{K} c_{i,k} f_k,
\]

for the \(i\)-th component of the vector field, one arrives at a system of \(N\) linear equations for each time step by inserting Eq. (2) into Eq. (1):

\[
\frac{d}{dt}X_i(t_l) = \sum_{k=1}^{K} c_{i,k} f_k(X(t_l)).
\]

If the time derivatives on the left hand side of Eq. (3) can be computed, this defines a linear system

\[
Y_i = Xc_i,
\]

where \(Y_i \in \mathbb{R}^N\) contains the time derivatives at all sampled time steps, \(X \in \mathbb{R}^{N \times K}\) contains the evaluations of all basis functions in dictionary \(\Theta_K\) at all time steps, and \(c_i \in \mathbb{R}^K\) is the unknown vector of coefficients:

\[
Y_{i,l} = \frac{d}{dt}X_i(t_l),
X_{i,k} = f_k(X(t_l)).
\]

Eq. (4) needs to be solved in the least-squares sense, that is, \(\tilde{c}_i\) becomes the minimizer of

\[
\tilde{c}_i = \min_{c_i \in \mathbb{R}^K} \|Y_i - X \cdot c_i\|_2^2.
\]
In general, the solution $\tilde{c}_i$ of Eq. (5) will not be sparse. If the goal is to find the functional form of the vector field that better represents the data among the large number of possibilities offered in the function dictionary, sparsity of $\tilde{c}_i$ needs to be enforced. Formally, this can be achieved by penalizing the $L^1$-norm of the solution and minimizing

$$\tilde{c}_i = \min_{c_i \in \mathbb{R}^K} (\|Y_i - X c_i\|_2^2 + \rho\|c_i\|_1),$$

using some positive Lagrange multiplier $\rho$ which controls the weight of the sparsity constraint. Algorithms to solve Eq. (6) will be discussed below.

B. Sparse Identification of Stochastic Dynamics

a. Diffusion Processes In this work, we extend the sparse learning framework discussed above to stochastic dynamics. Instead of Eq. (1), we consider dynamics driven by an Ito stochastic differential equation (SDE)

$$dX(t) = b(X(t))dt + \sqrt{2}\beta^{-1}\sigma(X(t))dW_t,$$

(7)

Again, $X(t) \in \mathbb{R}^d$ denotes the state of the system at time $t$, while $b : \mathbb{R}^d \mapsto \mathbb{R}^d$ is a vector field called the drift, and $\sigma : \mathbb{R}^d \mapsto \mathbb{R}^{d \times d}$ is a matrix field called the diffusion of the process. Moreover, $W_t$ denotes a $d$-dimensional Brownian motion, and the prefactor $\beta$ is the inverse temperature $\beta = \frac{1}{k_B T}$ in physical applications. The covariance matrix of the diffusion is commonly denoted by $a \in \mathbb{R}^{d \times d}$,

$$a(x) = \sigma^T(x)\sigma(x).$$

We will also refer to a process like Eq. (7) as a diffusion process. We assume the process $X(t)$ to be ergodic w.r.t. a unique invariant measure $\mu$.

A familiar variant of such a process is the overdamped Langevin dynamics

$$dX(t) = -\nabla U(X(t))_\gamma dt + \sqrt{2\beta^{-1}\gamma} dW_t,$$

(8)

that is, the drift is the gradient of a potential energy function $U$ (the force) normalized by the friction coefficient $\gamma$, while the diffusion matrix is constant. The equilibrium distribution associated to this dynamical process is the Boltzmann distribution: $\mu(x) \propto \exp(-\beta U(x))$.

A diffusion process is thus generally defined by two components, the drift and the diffusion. Both of them can be estimated from data via the Kramers-Moyal expansion.\footnote{Kramers-Moyal expansion}
\[ b_i(x) = \lim_{s \to 0} \mathbb{E} \left[ \frac{1}{s} (X_i(s) - x_i)|X(0) = x \right], \quad (9) \]
\[ a_{ij}(x) = \frac{\beta}{2} \lim_{s \to 0} \mathbb{E} \left[ \frac{1}{s} (X_i(s) - x_i)(X_j(s) - x_j)|X(0) = x \right]. \quad (10) \]

The expectations above average the linear and quadratic variation of the process \( X(s) \), conditioned on starting at position \( x \) at time \( s = 0 \).

If the linear and quadratic time variations on the right hand sides of Eq. (9) and Eq. (10) can be computed, a regression problem analogous to Eq. (5) can be formulated and both drift and diffusion can be approximated as an optimal linear combinations of basis functions.

b. Projected Dynamics

In many physical applications, a diffusion process is not observed through its original state space (e.g. atomic coordinates), but through a projected space of lower dimension (e.g. dihedral angles or interatomic distances in macromolecular dynamics). In this case, it is desirable to learn a stochastic dynamical system defined only along the projected variables from the data, often called an effective dynamics, while discarding the other features. We now investigate this issue by following the projection formalism previously proposed in other works\textsuperscript{10,11}. It is important to note that there are many possible ways of defining an effective dynamics on projected variables (see ref. 11 for a discussion). In practice, an effective dynamics in the form of an Ito stochastic differential equation (that is, without memory terms) is meaningful if the projected variables capture the slowest dynamical processes and a separation of timescales exists in the system. In the following we assume this to be the case.

Assume the projection is realized by a map \( \xi : \mathbb{R}^d \mapsto \mathbb{R}^m, \ m \leq d \), and denote points in the projected space by \( z \in \mathbb{R}^m \). The level set of a point \( z \) is denoted by

\[ \Sigma_z = \{ x \in \mathbb{R}^d : \xi(x) = z \}. \]

The projected stationary distribution is obtained by averaging the equilibrium distribution \( \mu \) over the level sets \( \Sigma_z \):

\[ \nu(z) = \int_{\Sigma_z} \mu(x) J^{-1/2}(x) \, d\sigma_z(x), \]
where $J$ is the Jacobian determinant of the transformation $\xi$, and $\sigma_z$ denotes the surface measure on the manifold $\Sigma_z$. It can be shown that $\nu$ defines a probability measure on the low-dimensional space $\mathbb{R}^m$. Also, we can define a probability measure $\mu_z$ which restricts the equilibrium measure to a level set by

$$d\mu_z(x) = \frac{1}{\nu(z)}\mu(x)J^{-1/2}(x)\,d\sigma_z(x)$$

for $x \in \Sigma_z$. Like in the previous section, an effective dynamics on the lower-dimensional space $\mathbb{R}^m$ can now be defined by using the Kramers-Moyal expansion:

$$b^\xi_i(z) = \lim_{s \to 0} E\left[\frac{1}{s}(\xi_i(X(s)) - z_i) | X(0) \sim \mu_z\right],$$

$$a^\xi_{ij}(z) = \frac{\beta}{2} \lim_{s \to 0} E\left[\frac{1}{s}(\xi_i(X(s)) - z_i)(\xi_j(X(s)) - z_j) | X(0) \sim \mu_z\right].$$

The difference between these and Eqs. (9-10) is that the dynamics is observed along the projection $\xi$ here, and that the initial condition is replaced by starting the process from the distribution $\mu_z$ instead of starting deterministically at one point.

c. Convergence Result  Just as in section II A, we would like to model the components of the (effective) drift and diffusion terms by a linear combination of pre-selected basis functions. We show that, given equilibrium simulation data, we only need to compute the linear and quadratic variations for all data points and approximate these data by a linear regression, as the equilibrium sampling automatically takes care of the averages required in Eqs. (12-13). This is the essence of the following convergence result, which we prove in Appendix B. We introduce the following

**Theorem 1:** Let $\{X(t_1), \cdots, X(t_{N+1})\}$ be a d-dimensional time series from a diffusion process as Eq. (8) or Eq. (7), sampled with a uniform time window $s$. Furthermore, let $\Theta = (f_1, \ldots, f_K)$ be a dictionary of basis functions on the projected space $\mathbb{R}^m$. Define the database matrix $X = \Theta(X(t_i)) \in \mathbb{R}^{N\times K}$ and introduce the set of vectors $Y_i, Y_{ij} \in \mathbb{R}^N$ as:

$$Y_{i,l} = \frac{1}{s} \left[\xi_i(X(t_{l+1})) - \xi_i(X(t_l))\right]$$

$$Y_{ij,l} = \frac{\beta}{2} \frac{1}{s} \left[\xi_i(X(t_{l+1})) - \xi_i(X(t_l))\right] \left[\xi_j(X(t_{l+1})) - \xi_j(X(t_l))\right]$$

$\forall i, j = 1, \ldots, m$. Then, as $N \to \infty$, $s \to 0$, the solutions $\tilde{c}_i, \tilde{c}_{ij} \in \mathbb{R}^K$ of the regression
problems

\[ \tilde{c}_i = \min_{c_i \in \mathbb{R}^K} \| Y_i - Xc_i \|_2^2, \quad \forall i = 1, \cdots, m \]  
\[ (16) \]

\[ \tilde{c}_{ij} = \min_{c_{ij} \in \mathbb{R}^K} \| Y_{ij} - Xc_{ij} \|_2^2, \quad \forall i, j = 1, \cdots, m \]  
\[ (17) \]

converge to the coefficient vectors of the best approximation problems

\[ \tilde{c}_i = \min_{c_i \in \mathbb{R}^K} \| b_i^\xi - \sum_{k=1}^{K} c_{i,k}f_k \|_{L_2^2}, \quad \forall i = 1, \cdots, m \]  
\[ (18) \]

\[ \tilde{c}_{ij} = \min_{c_{ij} \in \mathbb{R}^K} \| a_{ij}^\xi - \sum_{k=1}^{K} c_{ij,k}f_k \|_{L_2^2}, \quad \forall i, j = 1, \cdots, m \]  
\[ (19) \]

in the space \( L_2^2 \) of square-integrable functions w.r.t. the measure \( \nu \).

C. Learning of Effective Potentials

In most physical applications, the dynamics of a system is determined by its potential energy, which is a physically intuitive quantity. For example, the overdamped Langevin dynamics in Eq. (8) is defined by the potential energy \( U \), which generates the drift via its gradient field. Learning the individual components of the drift separately as in Eq. (16) can pose a challenge in high dimensional systems, since there is no guarantee the learned components are generated by a scalar potential. To circumvent the problem, it is desirable to estimate the potential energy directly instead of its gradient.

Let us consider the overdamped \( d \) dimensional Langevin dynamics Eq. (8). We can introduce a dictionary of differentiable multivariate basis functions \( \Theta = (f_1, \ldots, f_K) \), and make the ansatz:

\[ U(x) = \sum_{k=1}^{K} c_k f_k(x) = \Theta(x) \cdot c, \]

Define a tensor \( \mathcal{D} \in \mathbb{R}^{d \times N \times K} \) and a matrix \( \mathcal{Y} \in \mathbb{R}^{d \times N} \) by

\[ D_{ilk} = \frac{\partial f_k}{\partial x_i}(X(t_l)), \]  
\[ (18) \]

\[ Y_{il} = \frac{1}{s}(X_i(t_{l+1}) - X_i(t_l)). \]  
\[ (19) \]
and consider the following regression problem:

$$\tilde{c} = \min_{c \in \mathbb{R}^K} \| Y - D \cdot c \|_2^2,$$

where multiplication above represents summation over the last dimension of $D$. We show in appendix C that the solution of such a regression problem converges to the best approximation of the gradient field by the linear combination

$$\nabla U(x) = \sum_{k=1}^K c_k \nabla f_k(x) = \nabla \Theta(x) \cdot c,$$

by construction.

For a general diffusion process Eq. (7), defining a generalized potential that links drift and diffusion is still possible, if the dynamics are reversible. In this case, there exists a scalar function, which we call free energy $F: \mathbb{R}^d \mapsto \mathbb{R}$ such that:

$$\frac{\partial}{\partial x_i} F(x) = \left[ a^{-1}(x) \left( \frac{1}{\beta} \nabla \cdot a_i - b \right) \right]_i. \quad (20)$$

Here, we use the notation $\nabla \cdot a_i$ to denote the divergence of the $i$-th row of the covariance matrix $a$. Eq. (20) also holds for the effective drift and diffusion $b^\xi, a^\xi$ after applying a projection $\xi$, because the effective dynamics discussed in the previous section inherits reversibility from the original dynamics. Therefore, we discuss the projected case in the following, as estimation of the full dynamics is a special case of this problem.

Since the gradient of $F$ in Eq. (20) now depends on two unknowns, we need to estimate one of them first before we can solve for the free energy gradient. Suppose we have used the regression of Eq. (17) to obtain an expression for each component of the diffusion matrix $a^\xi(x)$ as

$$a^\xi_{ij}(x) = \sum_{k=1}^K c_{ij,k} f_k. \quad (21)$$

This model allows to evaluate each component of the diffusion and its derivatives at every simulation point.

Next, we can use Eq. (20) and the convergence of linear variations to the effective drift to set up a regression problem for the free energy gradient as a linear combination of the vector fields $\nabla f_k$, i.e.

$$\nabla F = \sum_{k=1}^K v_k \nabla f_k.$$ 

The regression problem becomes

$$v = \min_{w \in \mathbb{R}^K} \| Y - Dw \|_2^2, \quad (22)$$
where $Y$ and $D$ are now given by

$$Y_{il} = \left[ (a^\xi)_{i}^{-1} (X(t_l)) \left( \frac{1}{\beta} \nabla \cdot a^\xi_i (X(t_l)) - e^s(X(t_{l+1}), X(t_l)) \right) \right]_i,$$

$$D_{il,k} = \frac{\partial f_k}{\partial z_i}(X(t_l)),$$

and $e^s$ is a $m$-dimensional vector of finite differences,

$$e^s_j(y, x) = \frac{1}{s} (\xi_j(y) - \xi_j(x)).$$

Please see Appendix C for the detailed proof.

### III. METHODS

Our goal is to find a sparse representation to the drift and diffusion term, which requires computing a sparse solution to the regression problem Eqs. (16-17). Standard regression can be biased towards sparse solutions by introducing a $L^0$ constraint (also known as subset selection) into the standard optimization process

$$\tilde{c} = \min_c \left( \|Y - Xc\|_2^2 + \rho \|c\|_0 \right)$$

where the 0-norm $\|c\|_0$ denotes the number of non-zero components in $c$.

Unfortunately, the minimization problem Eq. (23) is non-convex, which makes finding a solution a NP-hard task. One popular way around this problem is to relax the problem to a $L^1$-norm constraint, and a sparse solution can then be computed by using one of the many algorithms available, such as Lasso\cite{1760-0323-8-5-504, 10.1093/bioinformatics/bth352}, matching pursuit\cite{10.1093/bioinformatics/bth352}, and its orthogonal variant OMP\cite{10.1093/bioinformatics/bth352}, or elastic net\cite{10.1093/bioinformatics/bth352}, just to name a few. Independently of the specific protocol, the sparse solution will have some coefficients equal to zero.

In principle, any sparsity value can be enforced in the solution, by tuning the Lagrange multiplier $\rho$ in Eq. (23). However, only a subset of those values provide a representation of the data set that is both accurate and compact. For instance, we expect an excessively sparse solution $c$ to severely under-fit and a barely sparse solution to over-fit the data\cite{10.1093/bioinformatics/bth352}. An under-(over-)fitted model contains less (more) parameters than can be justified by that data, and both regimes should be avoided. For this reason, any algorithm enforcing sparsity needs to be complemented by a criterion that allows to assess whether a solution is still statistically meaningful and that signals whether the over-fitting or under-fitting regimes are entered, in
order to automatically select the sparsity level. We propose to use the statistical procedure of *Cross Validation*\textsuperscript{19} to select solutions with optimal sparsity.

We show in the following that when using Cross Validation sparsity can be automatically enforced with iterative algorithmic formulations such as the Stepwise Sparse Regressor. Despite its intrinsic simplicity and intuitive interpretation, such an algorithm appears robust and effective, as it is discussed below.

### A. Sparsity enforcement

The approach we employ to solve the sparse regression Eq. (23) for stochastic systems is inspired by the iterative thresholding algorithm proposed by Brunton *et al.* in their deterministic SINDy study\textsuperscript{4}, which works as follows. First, a standard unconstrained linear regression is solved to compute a non-sparse solution $\tilde{c}$. Then, coefficients with a magnitude smaller than a pre-defined threshold value $\lambda$ are set to zero and regression is performed on the remaining coefficients, and the procedure is iterated till no coefficients are found smaller than $\lambda$. The threshold parameter $\lambda$ is a sparsification knob which needs to be tuned appropriately. While such an algorithm appears to produce good results in the identification of deterministic differential equations from data, it is not robust for the stochastic case.

We modify the thresholding approach to enforce sparsity iteratively by removing only one coefficient in every iteration, and use Cross Validation to select the number of iterations, as it is discussed in the next section. This modification removes the need of adjusting an external parameter like $\lambda$. The pipeline works as follows:

- **A standard least square regression**

  $$\tilde{c} = \min_{c \in \mathbb{R}^K} \| Y - Xc \|_2^2$$

  is solved to determine a preliminary (non-sparse) solution $\tilde{c}$.

- **One coefficient is set to zero.** Different criteria can be used to select the coefficient to remove, for instance the one with the smallest value can be deterministically chosen, i.e.

  $$\tilde{c}_i = 0 : i = \min_k |\tilde{c}_k|$$

  This way the level of sparsity is increased at every iteration.
• Standard regression is performed again on the remaining degrees of freedom

\[ Y = X[:, \hat{i}] \hat{c}[\hat{i}] \]

where \( \hat{i} \) indicates the set of all dictionary indexes but \( i \), which has been removed.

• The procedure is iteratively repeated until Cross Validation indicates that the optimal sparsity level (i.e. number of iterations) \( \tilde{s} \) in the solution \( \hat{c} \) is reached.

We call this algorithm *Stepwise Sparse Regressor* (SSR), and introduce the shorthand notation

\[ SSR(X, Y)_k \]  

(24)

to indicate the solution \( c \) obtained upon running the algorithm on \( k \) iterations. Such a solution is \( k \)-sparse, e.g. has \( k \) zero coefficients and \( n = K - k \) non-zero coefficients. In the following, we are going to refer to the parameter \( n \) as the *solution size*, while discussing the results.

Once Cross Validation is used to identify the number of iterations corresponding to the optimally sparse solution, the algorithm is parameter free and does not require any preliminary training phase before use.

**B. Cross Validation**

The specific number of iterations on which the Stepwise Sparse Regression needs to be run to find the optimal solution is determined by a *Cross Validation* (CV) calculation\(^{20}\), a statistical validation technique that has risen to great popularity in the interdisciplinary fields of model and hyperparameter selections (see ref. 18 for an introductory self contained discussion). The underlying idea is straightforward and summarized below.

Let us assume we have a family of parametric models \((M(\lambda_1), \ldots, M(\lambda_r))\) depending on a hyperparameter \( \lambda \) which takes values \( \lambda_1, \ldots, \lambda_r \) and we would like to select the one model that fits best a given data set \( D \). In the original CV formulation, the full data set is split into two disjoint subsets, and each model in the family is alternatively trained on one of them first and then tested on the other. The *cross validation score* is the average deviation \( \delta \) of the predictions of the trained model from the actual test set, and it measures
how accuracy and predictivity are balanced in that model. The set of parameters yielding low values of $\delta$ are selected and identify "optimal" models in the family.

Here, we use CV to select the size $n$ of the optimal solution to the linear regression problem Eq. (23), which plays the role of the hyperparameter $\lambda$ from the last paragraph. The family of models to validate is now a set of SSRs with different solution size $n = K - q$ (or, equivalently, different sparsity $q$), i.e.

$$\{SSR_q\}_{q=1,\ldots,K},$$

where the notation introduced in the previous section is used. CV is run on each model to generate a family of cross validation scores $\delta[SSR_q]$.

We use a $k$-fold cross validation formulation, where the full dataset is split into $k$ subsets, each of them playing alternatively the role of test set in a $k$ step procedure. Let us start by partitioning the dataset $\mathcal{D}$ containing $N$ data points $p$ into $k$ disjoint equivalent subsets $A_i$, which are selected randomly, i.e. $\bigcup_i A_i = \mathcal{D}, \ A_i \cap A_j = \emptyset$. Moreover, let us introduce the shorthand:

$$X_{A_i} = X[p_{A_i},:] , \quad p_{A_i} = \bigcup_{p \in A_i} p$$

Then, the cross validation score for each model $SSR_q$ is defined as an average

$$\delta^2[SSR_q] = \frac{1}{k} \sum_{i=1}^{k} \left\| Y_{A_i} - X_{A_i} \cdot SSR(X_{B_i}, Y_{B_i})_q \right\|^2_2$$  \hspace{1cm} (25)

$$B_p = \bigcup_{i \neq p} A_i$$  \hspace{1cm} (26)

where $SSR(X_{B_i}, Y_{B_i})_q$ indicates the $q$-sparse linear combination coefficients generated by running SSR on the training set $B_i$ (see notation Eq. (24)), which are then used to make a prediction $X_{A_i} \cdot SSR(X_{B_i}, Y_{B_i})_q$. The set of $\delta[SSR_q]$ is then monitored as a function of the solution size $n = K - q$, which usually results in a a behavior close to that represented in Fig. 1. We expect an intermediate regime of low cross validation score (accurate) solutions (region (2)) with variable sparsity: all such solutions are equally good at balancing sparsity and accuracy. In addition, this regime is bounded from the right and left by and under- and over-fitting regime (regions (1) and (3)) respectively . Solutions belonging to both regimes are characterized by larger values of the cross validation scores, which indicate that accuracy is decreasing. Intuitively, the one solution separating regime (2) from regime (1) is what we
FIG. 1. Cartoon representation of the expected behavior of the \( k \) fold cross validation score \( \delta[SSR_n] \) as a function of the solution size \( n \) in the linear combination solution.

call optimally sparse \( \tilde{n} \), since:

\[
\frac{\delta[\tilde{n} - 1]}{\delta[\tilde{n}]} \gg 1, \quad \frac{\delta[\tilde{n}]}{\delta[\tilde{n} + 1]} \approx 1
\]

The \( \tilde{n} \to \tilde{n} + 1 \) gap in the \( \delta \) values is a clear signal that increasing sparsity by one additional unit compromises the model predictive power.

In the following, the optimally sparse solution \( \tilde{n} \) is chosen by identifying such a transition point in the cross validation score curves. All cross validation calculations reported below were performed using Python routines available in \textit{sklearn}\textsuperscript{21}.

IV. HOMOGENEOUS DIFFUSION IN A DOUBLE WELL POTENTIAL

We illustrate our sparse regression protocol by applying it to overdamped homogeneous diffusion data in a one dimensional double-well polynomial potential Fig. 2:

\[
U(x) = \frac{1}{2}x^4 - 4x^3 + 9x^2 - 3x, \quad \frac{dU}{dx} = 2x^3 - 12x^2 + 18x - 3
\]  

(27)

to recover the drift of the process from the data. Five independent trajectories were generated by integrating Eq. (8) using the gradient in Eq. (27). We computed the time increments Eq. (14) and averaged them over discrete bins as explained in Appendix A.1. We illustrate the performance of the sparse regression on two different dictionaries \( \Theta \) and \( \Theta' \). Each dictionary consists of \( K = 20 \) basis functions of the form \([1, x, x^2, x^3, \cdots]\). Details about the
FIG. 2. Potential energy profile $U(x)$ (left panel) and its gradient $U'(x)$, which equals the opposite of the force (right panel).

dataset and the specific composition of the two dictionaries are provided in the Appendix, Eqs. (A2) and (A3). The first four entries in both databases correspond to the functions composing the drift term used to generate the data, $[1, x, x^2, x^3]$. We refer to the these four functions as analytic basis functions in the following.

Fig. 3a shows the cross validation score $\delta_{\Theta}$ from Eq. (26) for the first dictionary, $\Theta$, as a function of the solution size $n$. As the number of surviving coefficients $n$ decreases (from right to left), the cross validation score stays constant; however, going from a four term $n = 4$ to a three term $n = 3$ solution causes the cross validation score to increase by several orders of magnitude, which suggests that sparsity is now too extreme and compromises the model predictivity. The signal is clear, as indicated by the plot of ratios $\delta[n-1]/\delta[n]$ as a function of $n$ (inset in Fig. 3a). The position of the gap in the CV score curve suggests that $n = 4$ is the optimal solution sparsity, which is associated with a $\hat{\delta}_{\Theta} = 1.49 \cdot 10^{-4}$ CV score.

Fig. 3b shows the sparsity progress matrix, which monitors the linear combination status as a function of sparsity. The $(i, j)$ entry in the matrix refers to the function $f_i$ in the dictionary, when the solution only contains $n = j$ terms (i.e. after $20 - n$ iterations). The color code is as follows: grey pixels indicate that the coefficient $c_i$ is still alive, whereas white pixels are used for coefficients that have been removed. A horizontal black line indicates the optimal solution size $\tilde{n}$, as from the cross validation score plot, and the corresponding pixels are also colored in black. A light blue color is used to mark the analytic basis functions. Please note that no coefficient is resuscitated during the SSR iterations after it is removed from the dictionary in a previous iteration.
The optimal solution only contains the analytic basis functions and reads:

\[ \tilde{U}_\Theta'(x) = \tilde{c} \cdot \Theta(x) = -2.98 + 17.84x - 11.82x^2 + 1.96x^3 \]  

(28)

This expansion is an accurate approximation to Eq. (27), as it can be seen by comparing coefficients and from panel d in Fig. 3.

It is instructive to compare the optimal solution Eq. (28) to a slightly less sparse \( n = 5 \) and to a sparser \( n = 3 \) solution. The explicit expansions for these cases are:

\[ U_{n=5}'(x) = -2.98 + 17.43x - 11.75x^2 + 1.98x^3 + 0.4 \sin x \]  

(29)

\[ U_{n=3}'(x) = -2.88 + 14.5x - 3.89x^2 \]  

(30)

and are plotted together with the gradient Eq. (27) in Fig. 3c and Fig. 3e. The \( n = 5 \) solution contains the analytic functions and an extra small oscillatory term, and accurately approximates the gradient, \( \delta = 7.8 \cdot 10^{-5} \). In contrast, the sparser solution \( n = 3 \) is deprived of one key dictionary ingredient and does not perform well, as shown by panel e of Fig. 3 and the much larger cross validation score \( \delta = 9 \cdot 10^{-1} \).

Let us now discuss the solution to the problem Eq. (9) when a different dictionary \( \Theta' \) is used. Results are summarized in Fig. 4, using the same format as in Fig. 3.

The cross validation score plot in Fig. 4a shows a similar trend as in Fig. 3a, but a clear gap in the \( \delta \) values is now missing, and suggests that an optimal solution is somewhere in the range between \( n = 5 \) and \( n = 10 \). The transition point \( \tilde{n}_k = 7 \) is selected as the value of \( n \) maximizing the CV score ratio \( \delta[n-1]/\delta[n] \), as shown in the inset. It is worth noting that the maximum amplitude of the ratio is here two orders of magnitude smaller than in Fig. 3a. The progress matrix in Fig. 3b shows that the three analytic terms \( [x, x^2, x^3] \) are present in the optimal solution, but \( f_0 = 1 \) is not (first column), and there are additional contributions. The actual expansion \( \tilde{U}'(x) = \tilde{c}'\Theta'(x) \) reads:

\[ \tilde{U}'(x) = 17.85x - 12.68x^2 + 2.11x^3 + 9.61 \exp(-50(x-3)^2) + 
\]  

\[ -2.97 \exp(-50(x-4)^2) - 18.77 \exp(-0.6(x-4)^2) + 
\]  

\[ + 12.97 \left[ \tanh^2(x-4) + 1 \right] \]  

(31)

Performing a CV score based SSR on the two different dictionaries produces two solutions with different levels of sparsity and cross validation scores. Both of them succeed at capturing the double well feature Fig. 3c and Fig. 4c: of the potential Eq. (27). As a matter of fact, a
FIG. 3. Results from applying the SSR algorithm to a trajectory generated by diffusion in the potential of Eq. (27), using a function dictionary $\Theta$. (Panel (a)) Cross validation score is plotted as a function of solution size $n$. The inset shows the ratio $\delta[n]-1/\delta[n]$ as a function of $n$. Vertical red lines indicate the number of non-zero coefficients $\tilde{n}=4$ in the optimal solution. (Panel (b)) Sparsity progress matrix: any $(i,j)$ (grey) white entry indicates that coefficient $c_i$ is (non) zero after $K-j$ ($K=20$) iterations. A horizontal black line indicates $\tilde{n}$, and the corresponding coefficients are colored in black. The four dictionary basis functions $[1, x, x^2, x^3]$ have survived, and are highlighted in a blue color. (Panels (c)-(e)) Comparison between the exact gradient $U'(x)$ (black solid line) and solutions $\tilde{U}'(x) = \sum_k \tilde{c}_k f_k(x)$ (blue solid lines) with decreasing solution size $n$ values (or increasing sparsity, from left to right). Red markers represent the binned time increments as from Eq. (9).

Taylor expansion of the $\Theta'$-solution Eq. (31) returns a polynomial series which is consistent with Eq. (28).

However, the solution associated with dictionary $\Theta'$ is less parsimonious than what was found for the dictionary $\Theta$ considered above, and it is associated with a larger cross validation score

$$\tilde{\delta}_\Theta = 1.49 \cdot 10^{-4} < \tilde{\delta}_{\Theta'} = 5.6 \cdot 10^{-3}.$$ 

For this reason, the solution for dictionary $\Theta$ should be favored over $\Theta'$. We show in the next section that even if different dictionaries return different optimal solutions, the comparison of
FIG. 4. Sparse regression results for a dictionary \( \Theta' \neq \Theta \), using the same notation and color code as in Fig. 3. (Panel (a)) Cross validation score as a function of solution size \( n \). The inset shows the ratio \( \delta[n-1]/\delta[n] \) as a function of \( n \). Vertical red lines indicate the number of non zero coefficients \( \tilde{n}' = 7 \) in the optimal solution. (Panel (b)) Sparsity progress matrix. (Panels (c)-(e)) Comparison between the exact gradient \( U'(x) \) (black solid line) and solutions \( \tilde{U}'(x) = \sum_k \tilde{c}_k \Theta'(x) \) (blue solid lines) with decreasing solution size \( n \) (or increasing sparsity, from left to right). Red markers represent the binned time increments as from Eq. (9). Even though \( \tilde{c} \neq \tilde{c}' \), the gradient is still accurately approximated.

results for different dictionaries leads to the identification of the maximally sparse solution.

A. Greedy search

The results discussed above indicate that the performance of the SSR algorithm is affected by the composition of the dictionary used. The resulting optimal solutions are quantitatively different but qualitatively very similar to one another. This section is devoted to investigating this issue systematically.

The comparison of Fig. 3 and Fig. 4 shows that the cross validation signature when the SSR identifies the correct (maximally sparse) solution is much stronger than for the case of a less sparse solution.
This consideration suggests that, instead of proceeding by iteratively removing functions
from the dictionary, cross validation could be used to extensively test all possible combi-
inations of basis functions and compare the results to determine the maximally sparse
solution. That is, given a large reference dictionary, all possible combinations of functions
(with a given sparsity) could be considered, and the corresponding CV-score estimated and
compared.

We illustrate this idea by defining a large reference dictionary Ω of $M = 100$ basis
functions. The two previously used dictionaries are included in this large one $\Theta, \Theta' \subset \Omega$. The standard (non-sparse) linear regression problem

$$c_\theta = \min_c \|Y - X_\theta c\|_2^2$$

can be solved for each sub-dictionary $\theta \subset \Omega$ with $n < M$ functions, and the associated cross
validation score $\delta_\theta$ can be computed. If the $\delta_\theta$ values for all possible sub-dictionaries $\theta \subset \Omega$ and different $n$ values are tabulated, the optimal solution can be identified by comparing the
change in cross validation as a function of the dictionary size. Such a procedure evaluates
and compares different levels of sparsity in a greedy fashion and can in principle replace the
need of an iterative sparse regression algorithm.

For a very large reference database of $M$ functions, such a brute force approach becomes
computationally very demanding as the number of different sub-dictionaries with $n$ functions
is given by the binomial coefficient $C_{M,n} = \binom{M}{n}$, which becomes untreatable if $n \gg 1$. In
order to demonstrate the approach, we randomly sample $m_n$ different $n$-function dictionaries
$\theta$ from $\Omega$, for increasing values of $n$, and run CV validation on each of them (details on specific
values of $m_n$ are given in the Appendix).

The main results are shown in Fig. 5, where the cross validation scores $\delta_\theta$ (averaged over
several realizations, as detailed in the Appendix) are plotted as a function of the dictionary
size $n$.

Each dictionary realization is described by an orange point $(n, \delta_\theta)$, unless the analytic
basis functions $[1, x, x^2, x^3] \subset \theta_n$, in which case the point is blue. The minimum cross
validation score was selected (marked in black in Fig. 5) across all points for each dictionary
size $n$, and the resulting curve is plotted using a dashed black line.

Fig. 5 shows that the optimal sparse solution $\tilde{\theta} = [1, x, x^2, x^3]$, which is associated with
$\delta = 1.49 \cdot 10^{-4}$ (as also obtained for the $\Theta$-solution in the last section), clearly represents
FIG. 5. Greedy search in the solution space to the regression problem, Eq. (23), applied to the two-well potential, Eq. (27). For a given size $n$, the cross validation score for a set of 100 different dictionaries $\delta_{\theta,n}$ (subsets of the large reference dictionary $\Omega$) are plotted. Each marker represents a dictionary instance, and is colored in blue if the dictionary contains the analytic basis functions $[1, x, x^2, x^3] \subseteq \theta$, or in orange otherwise. The minimal (optimal) cross validation score $\min(\delta_k)$ over all realizations with a given size $n$ is indicated with a black dashed line. A vertical red line indicates the solution with optimal sparsity, as determined by the peak in the function $\delta[n-1]/\delta[n]$, as shown in the inset and represents the optimally sparse solution $\tilde{\theta} = [1, x, x^2, x^3]$.

The transition point in the cross validation curve. Any other $n = 4$ dictionary has a larger cross validation score, as signaled by the gap between the blue point and all other orange realizations at $n = 4$. Moreover, any sparser ($n = 3$) dictionary has an associated cross validation score larger by several orders of magnitude. The increase in CV score is a footprint that a dictionary is missing (at least) a key component (as in the cross validation score plots in Figs.3 and Fig. 4). As already observed before, less sparse solutions such as $5 < n < 20$ may reproduce the gradient of the potential equally good or slightly better and they all have comparable cross validation scores. When $n \gg 1$ (as the size of the dictionary increases), the cross validation scores start increasing, indicating the over-fitting regime.

The $\Theta'$ solution that was found in Fig.4 is represented by a $n = 7$ orange point in Fig. 5.
together with many others that share the same sparsity.

This greedy analysis shows that cross validation identifies the analytic basis functions \( \tilde{\theta} = [1, x, x^2, x^3] \) as the optimal sparse solution to the problem Eq. (16); sparser solution are less accurate (larger \( \delta \)), and comparably accurate solutions are less parsimonious (reduced sparsity), as indicated also by the plot of \( \delta[n-1]/\delta[n] \) as a function of solution size \( n \) (inset in Fig. 5).

This analysis calls attention to the shortcoming of the deterministic SSR algorithm to search for the optimal solution. As seen in the previous section the performance of SSR depends on the choice of the database. The deterministic nature of SSR is not always efficient in searching the solution space of the non-convex problem and SSR can be trapped in local minima that provide a sub-optimal solution.

The performance of the SSR algorithm can not be \textit{a priori} estimated by considering indicators of the ill-conditioning of the dictionary. For the example of the two dictionaries \( \Theta \) and \( \Theta' \) used in the previous section the condition number \( \kappa \) of the database does not reflect their performance, as

\[
\kappa(\mathbb{X}_{\Theta}) \approx 10^7, \quad \kappa(\mathbb{X}_{\Theta'}) \approx 10^3.
\]

At the level presented here, the proposed CV-based SSR is effective at relaxing to a sparse (even if not always the sparsest) solution which is dictionary dependent but which still efficiently captures the main features of the gradient.

**B. Effects of sampling noise on algorithmic performance**

In this section we investigate to what extent the convergence of the sparse regression algorithm is influenced by the presence of noise in the stochastic system, by using the double well potential Eq. (27) as a reference system. One of the main assumptions underlying the proof of Theorem 1 is that the data points are Boltzmann distributed. However, this condition is met only approximately on a finite size trajectory.

In order to investigate how deviations from the Boltzmann distribution affect the performance of the algorithm, we bin the trajectory along the x-axis in \( Q \) bins and introduce the bin-dependent relative error:

\[
\epsilon_i = \left| \frac{Y_i - U'(\bar{x}_i)}{U'(\bar{x}_i)} \right| \tag{32}
\]
| $\log_{10}f$ | 0 | −3 | −6 | −9 | $-\infty$ |
|---|---|---|---|---|---|
| % | 0 | 0 | 46 | 81 | 94 |

TABLE I. Percentage of dictionaries for which SSR converges to the optimal solution $[1, x, x^2, x^3]$, as a function of the noise scaling factor $f$, Eq. (32). $f = -\infty$ is a shorthand indicating no sampling noise.

where $Y_i$ is the average of the time increments Eq. (14) associated with bin $i$, and $\bar{x}_i$ is the bin center, see also Eq. (A1). The median of the error distribution $\{\epsilon_i\}_{i=1,\ldots,Q}$ over the trajectory sample used in the previous sections is approximately $10^{-2}$ and the largest deviation is found for the bin located on the top of the energy barrier (see Fig. 2). The error could be decreased by running longer trajectories or lowering the temperature of the system. Here we mimic these effects by generating new samples $\hat{Y}_i$ in every bin $i$ with increasingly smaller deviation from the ideal sample, using a scaling factor $f < 1$:

$$\hat{Y}_i^f = U'(\bar{x}_i) \mathcal{N}(0, \zeta), \quad \zeta = f \cdot \text{median}(\epsilon).$$

(33)

The noise distribution $\mathcal{N}$ was chosen to be Gaussian to approximate the effect of thermal noise. In practice the same effect could be obtained by running umbrella sampling simulations in every bin. The sparse regression was then run on this new, less noisy data set, for 100 different random 50 basis function dictionaries $\Theta$ (all including $[1, x, x^2, x^3]$ entries) and different values of the scaling parameter $f$. The performance of the SSR algorithm as a function of the sampling error is reported in Tab. I.

While for large sampling errors the SSR algorithm converges to the optimal solution $[1, x, x^2, x^3]$ for none of the 100 randomly selected dictionaries, the percentage of dictionaries where the optimal solution is found by the SSR increases as the sampling noise is reduced. Surprisingly, a handful of dictionaries still relax to a sub-optimal minimum even in the absence of noise.

This result indicates that for stochastic systems the sampling quality plays an important role in determining whether the SSR algorithm gets trapped in a local minimum in the solution space. Additionally, the effect of the noise reduction is dictionary-specific, as some dictionaries do not reach the global minimum till extremely low level of noise.
In practice, relevant (usually high-dimensional) systems will present large sampling errors, and a more robust algorithm for the search in the solution space is needed.

V. “LEARNING” A PROJECTED DYNAMICS

![Contour plot](image.png)

FIG. 6. A contour plot $U = U(x, y)$ of the lemon slice potential Eq. (34) is shown. Seven angular minima $\kappa = 7$ can be clearly distinguished. Details are given in the text.

We apply the analysis protocol discussed in the previous sections to "learn" the sparse stochastic dynamics along an effective coordinate. As a benchmark, we use a system where the solution can be computed analytically, that is, the two dimensional lemon slice potential introduced by Bittracher et al., which is specified by the polar representation $(\theta, r)$:

$$U(r, \phi) = \cos(\kappa \phi) + 10(r - 1)^2 + \frac{1}{r^2}$$

where $\kappa = 7$ indicates the number of minima in the energy landscape, as shown in Fig. 6.

It was previously shown that the polar angle $\phi \in [-\pi, \pi]$ correlates with the first seven eigenvectors of the backward Fokker Planck operator associated with this potential, which describe the basin hopping motions. The polar angle $\phi$ is then a good candidate for an effective coordinate. Projecting the overdamped diffusion into this coordinate results in the projected dynamics:

$$d\phi_t = b(\phi)dt + \sqrt{2}\beta^{-1}a(\phi)d\eta(t)$$

$$b(\phi) = \frac{C_r}{Z_r} \kappa \sin \kappa \phi, \quad a(\phi) = \frac{C_r}{Z_r}$$

(35)
FIG. 7. Sparse regression results for both drift $b$ (upper panels), and diffusion $a$ (lower panels) are summarized, using the same notation and color code as in Fig. 3. (Panels (a) and (d)) Cross validation score $\delta$ as a function of the solution size $n$, with vertical red lines indicating the optimal solutions $\tilde{n}_b$ and $\tilde{n}_a$. (Panels (b) and (e)) Sparsity progress matrices, where entries associated to the analytic functions are highlighted with color. (Panels (c) and (f)) Comparison between actual drift (diffusion) as from Eq. (35) (black line) and the optimal sparse representations $\tilde{b}(\phi)$ ($\tilde{a}(\phi)$) obtained with the SSR algorithm (blue). Red markers are used to indicate estimation from sampling according to Eqs. (12-13).

with the constants:

$$C_r = \int_0^\infty r^{-1} \exp \left[ -10\beta(r-1)^2 - \beta/r \right] dr$$

$$Z_z = \int_0^\infty r \exp \left[ -10\beta(r-1)^2 - \beta/r \right] dr$$

$$\frac{C_r}{Z_r} = 0.94, \quad \frac{C_r}{Z_r} \kappa = 6.61$$

(36)

Both the effective drift $b(\phi)$ and diffusion term $a(\phi)$ are shown in Fig. 7 as a reference, as black lines.

A stochastic trajectory was generated by simulating a diffusion process in the two-dimensional potential Eq. (34), and the binned averages of Eqs. (14-15) were computed from the simulation data, see appendix A1. The time increment $s$ was chosen to be equal to
V. DISCUSSION

The CV-based sparse regression method SSR presented above appears to be effective at learning stochastic dynamical equations. Indeed, the CV analysis allows to identify the

the integration step. A dictionary $\Theta''$ of $K = 20$ basis functions was used, with composition given in the Appendix, Eq. (A4). The dictionary includes the analytic functions for both $b$ and $a$, $[1, \sin 7\phi]$, Eq. (35), to which we refer as analytic basis functions, as in the previous sections.

The SSR algorithm with cross validation was used to obtain a sparse expression for the estimated drift and diffusion terms. The results are summarized in Fig. 7, where the same notation as in Fig. 4 is used.

The cross validation score plots in Fig. 7a and Fig. 7d allow to locate the $\delta$ transition points and identify the optimal solutions to Eq. (16) and Eq. (17).

As $\delta[n]$ reaches its minimum at solution size $n = 1$ for both the drift and the diffusion, looking at the $\delta[n - 1]/\delta[n]$ ratio is hereby unnecessary.

The optimal sparsity values $\tilde{n}_b = 1$ and $\tilde{n}_a = 1$ are indicated by vertical red lines. The optimal solutions read as:

$$\tilde{b}(\phi) = \tilde{c}_b \cdot \Theta(\phi) = 6.39 \sin(7\phi), \quad \delta = 4.0 \cdot 10^{-2}$$

$$\tilde{a}(\phi) = \tilde{c}_a \cdot \Theta(\phi) = 0.95, \quad \delta = 2.0 \cdot 10^{-4}$$

as shown in the sparsity progress matrices in Fig. 7b and Fig. 7f.

Enforcing sparsity isolates the analytic functions in the dictionary and makes the solutions of Eq. (38) analogous to Eq. (35), as shown in the comparison plots Fig. 7c and Fig. 7f.

We simulated the “learned” projected dynamics $d\phi_t = \tilde{b}(\phi)dt + \sqrt{2\tilde{a}(\phi)\beta^{-1}}dW_t$ using the same simulation parameters as in the original dynamics (Eq. (8) with the potential of Eq. (34)). We discretized the trajectory data and performed a Markov State Model analysis. Fig. 8a shows that the first few timescales of the original dynamics (dashed lines) are accurately recovered by the learned projected dynamics (solid lines). Also, the $\phi$-projected equilibrium distributions of both dynamics agree, as shown in Fig. 8b. Thus, the learned projected dynamics recovers both the full thermodynamics and long timescale kinetics of the original dynamics.

VI. DISCUSSION

The CV-based sparse regression method SSR presented above appears to be effective at learning stochastic dynamical equations. Indeed, the CV analysis allows to identify the
FIG. 8. Comparison between the kinetics and thermodynamics from both the analytic and the data-learned φ projected diffusion. (Top panel) MSM implied timescales plotted as function of the lag time $\tau$: horizontal dashed lines indicate the actual timescales of the full system. Deviations between the two dynamics (solid lines) are minimal. (Bottom panel) The stationary distributions $\exp\left(-\beta F(\phi)\right)$ of both the analytic (blue solid line) and the reconstructed dynamics ($\tilde{b}, \tilde{a}$) (dashed line with markers indicating the bin centers) are compared: oscillation frequency is matched exactly, and there is a minimal deviation in the amplitudes because of sampling errors, particularly close to the top of the oscillation.

The optimal solution as sparsity is maximized while the model predictive power is preserved. The key features of the drift and the diffusion components (e.g., the dynamics) are shown to be preserved.

For the one dimensional potential Eq. (27), the optimal solution closely approximates the gradient of the potential, as shown in Fig. 3d and Fig. 4d. Similarly, the optimal sparse solution for the lemon slice projected dynamics reproduces the thermodynamics and the long timescale kinetics of the original model, (see Figs. 7c, 7f, and 8).

However, the performance of the SSR algorithm and the specific form of the optimally sparse solution depend on the composition of the dictionary of basis functions used (e.g., compare $\tilde{c}$ in Fig. 3b with $\tilde{c}'$ in Fig. 4b). The “correct” solution $\tilde{\theta} = [1, x, x^2, x^3]$ can be ob-
tained if the solution space is searched greedily, but the SSR algorithm may return solutions corresponding to local minima and multiple function dictionaries need to be considered.

Using ill-conditioned dictionaries containing collinear basis functions exacerbates the convergence problem as multiple linear combinations are almost equivalent, and picking one over others is driven by small perturbations due to numerical noise.

Building a dictionary of strictly linearly independent basis functions (such as Hermite polynomials or Fourier series) is a well established strategy to avoid the “many-solution” problem from the very beginning. Another popular approach is to run singular value decomposition (SVD) on the regressor matrix and discard those singular values which are within machine precision (and therefore contribute exclusively to noise). The reduced set of truncated singular values naturally defines a space into which the regressor matrix can be projected. The regression can then be formulated in terms of new effective variables that are linear combinations of the original ones and are less noisy by construction; hence, more numerical stability is guaranteed. However, if the goal is learning a sparse representation of the potential energy driving a dynamical system, dictionary entries bear a physical meaning, and such interpretation may be lost upon SVD or orthogonalization. For instance, if the input coordinates are composed by a set of contacts or coordinates or angles in a macromolecule, linear combinations of such quantities may be far from being physically interpretable.

The main problem in the convergence of the SSR algorithm is that functions are pruned from the dictionary at every iteration in a deterministic fashion: whenever a given entry is removed from the database, it can not “resuscitate” in the next iterations, and the solution may be funneled into a local minimum. We believe that introducing stochasticity in the pruning of entries and allowing the reintroduction of previously eliminated entries, resembling Monte Carlo techniques, could significantly improve the performance of the algorithm and also compensate (at least partially) for collinearity.

Appendix A: Details

1. Binning

Solving sparse regression Eq. (23) usually involves computing, storing, and inverting large matrices (e.g. \(X, Y\)) which scale linearly with the number of frames in a trajectory \(N \gg 1\). If the dimension of the system is relatively small, e.g., \(d \approx 1\), the problem can be made more tractable numerically. Let us start by histogramming the coordinate \(X\) into \(Q\) bins, i.e.:

\[
\{X(t_i)\}_{i=1,\ldots,N} \mapsto \{\bar{x}_i, w_i\}_{i=1,\ldots,Q}
\]  

(A1)

where \(\bar{x}_i\) indicates the \(i\)th bin center and \(w_i\) indicates the fraction of data in the \(i\)th bin, which we call bin weight. Subsequently:

\[
X \in \mathbb{R}^{N \times K} \mapsto X_Q \in \mathbb{R}^{Q \times K}
\]

\[
Y \in \mathbb{R}^N \mapsto Y_Q \in \mathbb{R}^Q
\]

where \(Y_Q\) entries are averaged over each bin.

The sparse regression Eq. (23) can be cast in the following weighted regression

\[
\tilde{c} = \min_c \|W_Q Y_Q - W_Q X_Q c\|_2^2 + \lambda \|c\|_0
\]

where the weight matrix \(W_Q\) is defined as

\[
X_Q = \text{diag}(w_1, \cdots, w_Q)
\]

Both the double well potential and projected dynamics study cases discussed here are \(d = 1\) problems, and the binning is used in the results presented in the manuscript.

2. Double well potential

The data set \(\mathcal{D}\) used in the double well potential example consists of five long independent trajectories of \(N = 10^7\) steps each, generated by integrating the dynamics Eq. (8)
using a time increment \( s = 5 \cdot 10^{-3} \) with \( m = 1, k_B T = 1, \gamma = 1 \) (arbitrary units).
The simulations were sufficiently long to ensure sampling from the equilibrium distribution
\( \pi(x) \propto \exp(-U(x)) \), see Eq. (27).

Both the time sequence \( \{X(t_l)\}_{l=1,\ldots,N+1} \) and the set of simple increments, Eq. (14):

\[
\{Y_l\}_{l=1,\ldots,N} = \left\{ \frac{X(t_{l+1}) - X(t_l)}{s} \right\}_{l=1,\ldots,N}
\]

were discretized into \( Q = 90 \) bins along the \( x \) axis, giving rise to an increment matrix \( \mathbf{Y} \in \mathbb{R}^{Q \times K} \).

Two different \( K = 20 \) basis function dictionaries \( \Theta \) and \( \Theta' \) were considered. Both contain the four functions \([1, x, x^2, x^3] \) entering Eq. (27), the remaining entries were selected randomly from a larger set of 100 basis functions. The specific composition of the two dictionaries read:

\[
\Theta(x) = [1, x, x^2, x^3, x^4, \ldots, x^9, x^{10}, \sin x, \cos x, \\
\sin(6x), \cos(6x), \sin(11x), \cos(11x), \tanh(10x), -10 \tanh^2(10x) + 10 e^{-50x^2}]
\]

\[
(A2)
\]

\[
\Theta'(x) = [1, x, x^2, x^3, \sin x, \cos 11x, \sin 11x, -10 \tanh^2(10x) + 10, \\
-10 \tanh^2(10x - 10) + 10, e^{-50x^2}, e^{-50(x-3)^2}, \\
e^{-0.3x^2}, e^{-0.3(x-3)^2}, e^{-2(x-2)^2}, e^{-2(x-4)^2}, e^{-50(x-4)^2}, \\
e^{-0.6(x-4)^2}, e^{-0.6(x-3)^2}, -2 \tanh^2(2x - 4) + 2, \tanh^2(x - 4) + 1]
\]

\[
(A3)
\]

Each dictionary computed on the binned coordinate generates a database \( \mathbf{X} \in \mathbb{R}^{Q \times K} : X_{ij} = \Theta_i(\bar{x}_j), \bar{x}_j \) being the value of the coordinate in the \( j \)-th bin, Eq. (A1).

\( N_k = 50 \) independent cross validation calculations were run and the cross validation scores averaged:

\[
\delta^2 = \frac{1}{N_k} \sum_{k=1}^{N_k} \delta_k^2
\]

where \( \delta_k \) is given by Eq. (26). Each CV run, \( i \), is associated with its own decomposition of the data set into folds

\[
\mathcal{D} \rightarrow \{A^j_i\}_{j=1,\ldots,5}.
\]
3. Greedy sparsity search

We provide a short description of the parameters used in the greedy search in the solution space for the double well potential.

The number of independent dictionary combinations reads

\[
m_n = \begin{cases} 
C_{M,n} & \text{if } n \in [2, 3, 4] \\
10^5 & \text{otherwise}
\end{cases}
\]

Cross validation scores were computed by running \( N_k = 20 \) independent 5-fold cross validations, and averaging over all runs as already mentioned.

4. Projected dynamics

The dataset \( D \) for the lemon slice example consists of one single \( N = 10^7 \) step diffusive trajectory, generated by integrating dynamics Eq. (8) for \( U = U(x, y) \) using a time increment \( s = 10^{-3} \) with \( m = 1, k_B T = 1, \gamma = 1 \) (arbitrary units). The simulation was long enough to ensure equilibrium sampling. The projection coordinate is the polar angle \( \xi = \phi \).

Both the time sequence \( \{\phi(x(t_l), y(t_l))\}_{l=1,...,N+1} \), the simple increments Eq. (14)

\[
\{Y_b(\phi)\}_{l=1,...,N} = \left\{ \frac{\phi(t_{l+1}) - \phi(t_l)}{s} \right\}_{l=1,...,N}
\]

and the squared increments Eq. (15)

\[
\{Y_a(\phi)\}_{l=1,...,N} = \left\{ \frac{1}{2} \frac{(\phi(t_{l+1}) - \phi(t_l))^2}{s} \right\}_{l=1,...,N}
\]

were discretized into 63 bins along the \( \phi \in [-\pi, \pi] \) axis, giving rise to \( Y_a, Y_b \in \mathbb{R}^Q \).

A \( K = 20 \) basis function dictionary \( \Theta'' \) was considered, such that \( [1, \sin 7x] \in \Theta'' \), Eq. (35). Its specific composition reads:

\[
\Theta''(x) = [1, x, x^2, x^3, x^4, x^5, x^6, \sin x, \cos x \\
\sin 4x, \cos 4x, \sin 7x, \cos(7x), \tanh(10x), \\
-10 \tanh^2(10x) + 10, e^{-50x^2}, \tanh(2x), -2 \tanh^2(2x) + 2, \\
e^{-2x^2}, \tanh(x)]
\]
The functions in the dictionary computed on the binned coordinate generate a database
$X \in \mathbb{R}^{Q \times K} : X_{ij} = \Theta_i''(\bar{\phi}_j)$, $\bar{\phi}_j$ being the value of the coordinate in the $j$-th angular bin (notation from Eq. (A1)).

Cross validation scores were computed by running $N_k = 50$ independent 7-fold cross validations, and averaging over all runs as already mentioned.

Appendix B: Proof of Theorem 1

In order to prove Theorem 1, we need the following non-linear version of Fubini’s theorem, called the co-area formula:

$$\int_{\mathbb{R}^n} f(x) \, dx = \int_{\mathbb{R}^m} \int_{\Sigma_x} f(x) J^{-1/2}(x) \, d\sigma_z(x) \, dz.$$ 

The co-area formula implies that for functions $f$, $g$ which only depend on $z$, we have

$$\int_{\mathbb{R}^n} f(x) g(x) \mu(x) \, dx = \int_{\mathbb{R}^m} f(z) g(z) \nu(z) \, dz. \quad (B1)$$

Now, regression problems Eqs. (16-17) are equivalent to the normal equations

$$\Theta^T \Theta c_i = \Theta^T Y_i, \quad (B2)$$
$$\Theta^T \Theta c_{ij} = \Theta^T Y_{ij}. \quad (B3)$$

By ergodicity of the process and Eq. (B1),

$$\frac{1}{L} [\Theta^T \Theta]_{k,k'} = \frac{1}{L} \sum_{l=1}^{L} f_k(X(t_l)) f_{k'}(X(t_l))$$

$$\xrightarrow{L \to \infty} \langle f_k, f_{k'} \rangle_{\mu}$$
$$= \langle f_k, f_{k'} \rangle_{\nu}.$$ 

To calculate the asymptotic limits of the right-hand sides in Eqs. (B2)(B3), we use the conditional transition probability density $p_s(x, y)$ over time $s$, and introduce the quantities
\[ d_i^s(x) = \int_{\mathbb{R}^n} \frac{1}{s} [\xi_i(y) - \xi_i(x)] p^s(x, y) \, dy, \quad (B4) \]

\[ d_{ij}^s(x) = \int_{\mathbb{R}^n} \frac{1}{s} [\xi_i(y) - \xi_i(x)] [\xi_j(y) - \xi_j(x)] p^s(x, y) \, dy. \quad (B5) \]

We find for the right-hand side of Eq. (B2):

\[ \frac{1}{L} [\Theta^T Y]_k = \frac{1}{L} \sum_{l=1}^{L} f_l(X(t_l)) \frac{1}{s} [\xi_i(X(t_{l+1}) - \xi_i(X(t_l))] \]

\[ \xrightarrow{L \to \infty} \int_{\mathbb{R}^n} \int_{\mathbb{R}^n} \frac{1}{s} [\xi_i(y) - \xi_i(x)] p^s(x, y) \mu_k(x) \, dx \, dy \]

\[ = \int_{\mathbb{R}^n} d_i^s(x) f_k(x) \mu(x) \, dx \]

\[ = \int_{\mathbb{R}^m} \left[ \int_{\Sigma_z} d_i^s(x) \mu(x) J^{-1/2}(x) \, d\sigma_z(x) \right] f_k(z) \, dz \]

\[ = \int_{\mathbb{R}^m} \left[ \int_{\Sigma_z} d_i^s(x) \, d\mu_z(x) \right] f_k(z) \nu(z) \, dz \]

\[ \xrightarrow{s \to 0} \langle b_i^\xi, f_k \rangle_\nu. \]

In the fourth line, we have used the co-area formula, followed by the definition of the restricted equilibrium measure \( \mu_z \) in Eq. (11). The last step follows from the Kramers-Moyal formula Eq. (12). In the same way, we find that

\[ \frac{1}{L} [\Theta^T Y_{ij}]_k \xrightarrow{L \to \infty} \int_{\mathbb{R}^n} d_{ij}^s(x) f_k(x) \mu(x) \, dx \]

\[ \xrightarrow{s \to 0} \langle a_{ij}^\xi, f_k \rangle_\nu. \]

We conclude that Eqs. (B2), (B3) converge to the \( L^2_{\nu} \)-best-approximation problem for the effective drift and diffusion, \( b_i^\xi \) and \( a_{ij}^\xi \), using the basis set \( f_k \).

**Appendix C: Estimation of Potential Energy**

Here, we show that the regression problem Eq. (22) converges to the best-approximation problem for the generalized energy Eq. (20) from the basis set of vector fields \( \nabla f_k, k = 1, \ldots, K \). The case where no projection is applied can be recovered by choosing \( \xi \) as the
identity on $\mathbb{R}^n$, and the formulation we introduced for the overdamped Langevin dynamics is obtained by setting the diffusion to an identity matrix.

The proof is very similar to the previous section. Starting from the normal equation

$$D^T D v = D^T Y,$$

we first find that

$$\frac{1}{L} [D^T D]_{k,k'} = \frac{1}{L} \sum_{i,j} \frac{\partial f_k}{\partial z_i}(X(t_i)) \frac{\partial f_{k'}}{\partial z_j}(X(t_i))$$

$$\xrightarrow{L \to \infty} \sum_{i=1}^m \langle \frac{\partial f_k}{\partial z_i}, \frac{\partial f_{k'}}{\partial z_i} \rangle_{\mu}$$

$$= \langle \nabla f_k, \nabla f_{k'} \rangle_{\nu}.$$ 

Moreover, the data vector $D^T Y$ converges to

$$\frac{1}{L} [D^T Y]_k = \frac{1}{L} \sum_{i,l} \frac{\partial f_k}{\partial z_i}(X(t_i)) \left[ (a^\xi)^{-1}(X(t_i))(\frac{1}{\beta} \nabla \cdot a^\xi_i(X(t_i)) - e^s(X(t_{l+1}), X(t_i))) \right]_i$$

$$\xrightarrow{L \to \infty} \sum_{i=1}^m \int \int \frac{\partial f_k}{\partial z_i}(x) \left[ (a^\xi)^{-1}(x)(\frac{1}{\beta} \nabla \cdot a^\xi_i(x) - e^s(y, x)) \right]_i \mu(x)p^s(x, y) \, dx \, dy.$$ 

We can proceed exactly as in the previous section, recalling the vectors $d^s$ from Eq. (B4) and the relation between drift and diffusion, Eq. (20):

$$\frac{1}{L} [D^T Y]_k = \sum_{i=1}^m \int \frac{\partial f_k}{\partial z_i}(x) \left[ (a^\xi)^{-1}(x)(\frac{1}{\beta} \nabla \cdot a^\xi_i(x) - d^s(x)) \right]_i \mu(x) \, dx$$

$$= \sum_{i=1}^m \int \frac{\partial f_k}{\partial z_i}(z) \left[ (a^\xi)^{-1}(z)(\frac{1}{\beta} \nabla \cdot a^\xi_i(z) - \int_{\Sigma_z} d^s(x) \, d\mu_z(x)) \right]_i \nu(z) \, dz$$

$$\xrightarrow{s \to 0} \sum_{i=1}^M \langle \frac{\partial f_k}{\partial z_i}, (a^\xi)^{-1}(\frac{1}{\beta} \nabla \cdot a^\xi_i - b^\xi) \rangle_{\nu}$$

$$= \langle \nabla f_k, \nabla F \rangle_{\nu}.$$
