Abstract

Background: Podoconiosis is a neglected tropical disease (NTD) that is prevalent in red clay soil-covered highlands of tropical Africa, Central and South America, and northern India. It is estimated that up to one million cases exist in Ethiopia. This study aimed to estimate the prevalence of podoconiosis in East and West Gojam Zones of Amhara Region in northern Ethiopia.

Methodology/Principal Findings: A cross-sectional household survey was conducted in Debre Eliyas and Dembecha woredas (districts) in East and West Gojam Zones, respectively. The survey covered all 17,553 households in 20 kebeles (administrative subunits) randomly selected from the two woredas. A detailed structured interview was conducted on 1,704 cases of podoconiosis identified in the survey.

Results: The prevalence of podoconiosis in the population aged 15 years and above was found to be 3.3% (95% CI, 3.2% to 3.6%). 87% of cases were in the economically active age group (15–64 years). On average, patients sought treatment five years after the start of the leg swelling. Most subjects had second (42.7%) or third (36.1%) clinical stage disease, 97.9% had mossy lesions, and 53% had open wounds. On average, patients had five episodes of acute adenolymphangitis (ALA) per year and spent a total of 90 days per year with ALA. The median age of first use of shoes and socks were 22 and 23 years, respectively. More men than women owned more than one pair of shoes (61.1% vs. 50.5%; $\chi^2 = 11.6$ p = 0.001). At the time of interview, 23.6% of the respondents were barefoot, of whom about two-thirds were women.

Conclusions: This study showed high prevalence of podoconiosis and associated morbidities such as ALA, mossy lesions and open wounds in northern Ethiopia. Predominance of cases at early clinical stage of podoconiosis indicates the potential for reversing the swelling and calls for disease prevention interventions.

Introduction

Podoconiosis is a non-infectious elephantiasis distinct from lymphatic filariasis that affects barefoot individuals exposed to red clay soil of volcanic origin. In particular, podoconiosis is prevalent among barefoot subsistence farmers that live and work in these areas [1]. Even though the pathogenesis of the diseases has not yet been investigated in depth, it is believed to be caused by fine particles in the soil that penetrate the skin and induce an inflammatory reaction in the lymphatic system [2]. The disease results in bilateral progressive swelling of the lower legs, usually limited below the level of the knees. Based on the disease progression, podoconiosis is classified into five stages where the first and second stages have swelling limited below ankle which is either reversible over night (stage one) or not (stage two). The third stage of the disease has water bag like or nodular swelling above the level of the ankle. The fourth stage entails above knee swelling whereas the fifth stage involves joint fixation as a result of surrounding soft tissue overgrowth [3]. Podoconiosis can be identified clinically in endemic areas (above 1200 m) without the need to do laboratory tests because it usually presents with bilateral and asymmetric swelling on the lower limbs with rare groin involvement unlike the lymphatic form of elephantiasis [4]. Similarly, the nervous system is intact in podoconiosis and there is neither loss of sensation nor thickened nerves or trophic ulcers unlike leprosy [5,6]. Podoconiosis can be prevented, early forms of the disease can be treated, disease progression can be curbed and the disease can potentially be eliminated as a public health burden with low technology but effective measures such as washing feet with soap and water on a regular basis and wearing protective shoes consistently [7,8,9].

High prevalence of podoconiosis has been reported in many parts of highland Africa: Ethiopia [10], Cameroon [11], Rwanda [12], Burundi, Sudan [13], Uganda [14], Tanzania [15], Kenya [16], the islands of Bioko, Sao Tome and Principe [17], and Equatorial Guinea [18]. Up to one million cases are estimated to exist in Ethiopia, of whom one-third belong in the economically productive age group [10]. Recent studies in southern and western
Author Summary

Podoconiosis is non-infectious elephantiasis that affects barefoot people that have prolonged exposure to red clay soil. It is common in tropical Africa, central America and northern India. Podoconiosis presents as bilateral below knee swelling. Podoconiosis can be both prevented and controlled by consistently washing feet, wearing shoes, and using antiseptics and emollients. This survey is the biggest conducted to date in Ethiopia: 17,553 households in East and West Gojam Zones of northern Ethiopia were included, and 1,704 patients were identified. We interviewed patients in detail about manifestations of acute attacks (painful inflammation of the foot and leg with swollen lymph nodes and fever), clinical disease stage, treatment seeking, foot washing and shoe wearing practices. We found the prevalence of podoconiosis to be 3.3%. Most patients were farmers, uneducated and within the economically active age group. There was no gender difference in occurrence of podoconiosis and in foot washing practices. The onset of leg swelling and the age of first shoe wearing were similar. We also found delayed treatment seeking and many days confined to bed during acute inflammatory episodes. We conclude that podoconiosis imposes a huge burden in northern Ethiopia.

Ethiopia estimated the prevalence of podoconiosis to be 5.5% [10] and 2.8% [19], respectively.

Although the Amhara Region in northern Ethiopia is one of the regions burdened by podoconiosis in specific highland districts, there have been no recent studies to assess the prevalence, clinical features, and socio-economic burden of the disease. To our knowledge, the only two studies that provided data on the prevalence of the disease in Amhara region date back more than 40 years [20,21]. In June 2010, International Orthodox Christian Charities (IOCC), a non-government organization, started the first podoconiosis program in East Gojam Zone, Amhara Region. The program aims to address podoconiosis prevention, awareness, and care and support activities. To strengthen the services provided in East Gojam Zone and scale up to West Gojam Zone, there was an evident need for baseline data to direct the public health interventions. Therefore, the aim of this study was to assess the burden of podoconiosis in East and West Gojam Zones of Amhara Regional State, northern Ethiopia. Specifically, the study aimed to answer questions including, but not limited to, overall, gender- and age-specific prevalence; manifestations of acute attack episodes (acute adenolymphangitis or ALA: painful inflammation of the foot and leg with swollen lymph nodes and fever); clinical disease stage; treatment seeking behavior; and foot washing and shoe wearing practices of patients.

Methods

Ethics statement

Ethical clearance was obtained from the Amhara Regional Health Bureau. Support letters were obtained from East and West Gojam Zonal Health Departments and Woreda Health Offices. Oral informed consent was obtained from each study participant after reading the written consent form to them, since most of the respondents were not able to read and write. The interviewers confirmed the participant’s oral consent by signing on the respective consent form for each interview as per the guideline of the ethical review Board of the Amhara Regional Health Bureau. When children aged under 18 years (the legal age for giving consent for research in Ethiopia) were encountered, consent was obtained from their parents or guardians. The use of verbal consent was approved by the ethical review committee because the majority of the study participants cannot read and write.

Study design and study area

This study was a cross-sectional community-based house-to-house survey. The study was conducted in East and West Gojam Zones of Amhara Regional State. All villages (Kebelos) in known podoconiosis-endemic kebeles (the lowest level government administrative structure in Ethiopia) were included in the house to house case enumeration. Identification of the study area was based on a report by IOCC’s podoconiosis treatment center, written in 2010 summarizing information from key local informants. The study participants were residents of the selected kebeles and podoconiosis cases in all households with podoconiosis.

Sampling procedure and sample size determination

The Ethiopian administrative structure is organized hierarchically, with multiple Zones in each Region. Each Zone contains multiple Woredas (equivalent to districts). Each Woreda contains Kebelos and there are villages with multiple households in each Kebele. A convenience non-random sampling method was used to select two Zones. A list of woredas (government administrative units equivalent to districts) in East and West Gojam Zones, known for the presence of podoconiosis based on expert opinion and key informants, was prepared. Second, a random sampling technique was applied to select two woredas, one from each Zone. Third, kebeles from each of these two woredas were sampled randomly proportional to their population size in each woreda. A total of 20 kebeles from the two woredas in East Gojam and West Gojam Zones (7 kebeles from East Gojam and 13 kebeles from West Gojam) were selected. All households in the selected kebeles were assessed for the presence of podoconiosis cases through interviews with the household head followed by clinical examination of cases by community health extension workers (HEW). Households with podoconiosis cases were included for individual podoconiosis case interviews by clinical nurses. In households where there was more than one podoconiosis patient, all patients were interviewed, and physical examination and measurement of leg circumference were done.

Data collection process

Data collection was done house-to-house by trained HEWs supervised by nurses that work in the respective woredas. The HEWs were responsible for house-to-house enumeration of podoconiosis cases and the nurses were responsible for supervising the activities of the HEWs and the detailed assessment of podoconiosis cases (i.e., interviewing and physical examination of patients). All HEWs and nurses received training from the team of researchers before performing data collection. The training consisted of techniques and approaches for obtaining informed consent from prospective participants, interviewing techniques, podoconiosis diagnostic features, and staging according to a standard method [3], assessment of ALA, measurement of leg circumference (the largest circumference between the levels of the ankle and knee measured using a tape, to a precision level of the nearest centimeter [3]), assessment of presence of open wounds, and features that differentiate lymphoedema and leg swelling resulting from podoconiosis from other diseases such as leprosy and filarial elephantiasis. Furthermore, these data collectors were trained on how to advise patients to wear shoes and wash their feet to control disease progression at the end of every interview.
A pre-test of the actual data collection process and the data collection tools was conducted immediately after the training of the data collectors. The pre-test was done in two kebeles (one in West Gojam Woreda and the other in East Gojam Woreda) which were not included in the main survey. The pre-tests were evaluated in terms of (i) organization of the fieldwork and coordination between the team of investigators, supervisor nurses and HEWs; (ii) ability of the HEWs to effectively conduct the census and complete the questionnaires; (iii) ability of the supervisor nurses to correctly diagnose and stage podoconiosis, and identify ALA symptoms; (iv) completeness, skip patterns, flow and clarity of the questionnaire. At the end of the pre-test, the trainees brought back the data they collected to the training centre. The completed questionnaires were checked by the trainers. Discussion on the challenges the trainees faced during data collection and on the data collection tools was held and the questionnaires were revised accordingly.

Data collection tools
The data collection tool was a structured questionnaire. The questionnaire was developed in English, translated into Amharic and back translated into English to check consistency. The questionnaire was sub-sectioned thematically into socio-demographic characteristics, podoconiosis history, clinical features, foot hygiene and shoe wearing practices.

Data processing and analysis
Data were entered and analysed using the Statistical Package for Social Sciences (SPSS) software v.17.0. The overall prevalence of podoconiosis was calculated as the ratio of the number of patients with podoconiosis to the total population surveyed aged 15 years and over. Statistical significance was tested using the Chi-squared test or t-test as appropriate. The level of significance was set at α of 0.05.

Results
Socio-demographic characteristics
A total of 17,553 households with 51,017 members aged 15 years and above were included in the present survey. Of the surveyed households, 9.7% had one or more podoconiosis patients. A total of 1,319 podoconiosis patients that provided information on the number of ALA episodes in the year prior to the interview were covered in the survey. The median ages of first use of shoes and socks in the area were 15 and 16 years, respectively. About 40% of the patients said that they had one pair of shoes. More men than women owned more than one pair of shoes (61.1% vs. 50.5%; \(\chi^2 = 11.6, p = 0.001\)). Most study participants suggested that they need three pairs of shoes per year.

Features of acute adenolymphangitis (ALA)
On average, patients had five episodes of ALA per year and had 90 ALA morbidity days per year. Among patients who had ALA episodes more frequently than once per month (n = 329), 73.1% had ALA during the two weeks prior to the date of interview. Similarly, 94.4% of the ALA episodes reported in the year prior to the interview happened in the most recent six months. Nearly half of the participants (49.8%) had ALA during the interview. Physical examination of the interviewees that had ALA showed that hot (49.9%), tender (60.2%), swelling, and inguinal lymphadenopathy (62.1%) were common features.

Shoe-wearing, foot-washing and walking experience
The median ages of first use of shoes and socks in the area were 22 and 23 years, respectively. About 40% of the patients said that they had one pair of shoes. More men than women owned more than one pair of shoes (61.1% vs. 50.5%; \(\chi^2 = 11.6, p = 0.001\)). Most study participants suggested that they need three pairs of shoes per year.

The average walking time to the nearest field was 14.9 minutes (SD = 15.7). The average walking time to the nearest field and nearest market were 20 minutes (SD = 14.9) and 54.5 minutes (SD = 50.1), respectively. On average, the respondents travelled to their nearest field and to market nine (SD = 10.9) and four (SD = 3.9) times per month, respectively. On observation, 46.8% of patients had clean feet, 25.1% had dirty feet, 13.9% had cracked feet and 13.9% had both dirty and cracked feet. The reported average frequency of foot washing was seven times a week. There was no statistically significant difference between men and women in the frequency of foot washing (p = 0.12) and foot washing with soap (p = 0.33).
Discussion

This study presents the largest of all household surveys of podoconiosis in Ethiopia conducted over the past ten years. It is the first community-based study of podoconiosis in the Amhara region, the second largest region in Ethiopia. Men and women were equally affected by podoconiosis, as found in the Wolaita study (1:0.98) [10] but in contrast to the Gulliso (1:2.6) [19] and

#The proportion the population of 15 years and above, by sex, was calculated based on the Ethiopian Central Statistics Authority Report: 55.5% for Debre Eliyas Woreda, 58% for Dembecha Woreda, and 57.4% for Amhara Region [30].
do:10.1371/journal.pntd.0001744.t002
Ocholo (1:4.2) [22] studies. The prevalence of podoconiosis in the present study area (3.3%) was higher than the recent reports for Gulliso woreda in western Ethiopia (2.8%) [19] but lower than that reported among long-term residents in Ocholo village in southern Ethiopia (5.1%) [22], among resettlement scheme residents in Illubabor, western Ethiopia (9.1%), among residents in Gera and Dicessa towns in southern Ethiopia (8–10%) [23], among residents in Midakegn district, central Ethiopia [24], and in Wolaita, southern Ethiopia (5.5%) [10]. The prevalence falls within the earliest national estimate of 0.4% to 3.7% across fifty-six markets [20]. The prevalence of podoconiosis found in the present study was greater than the previous estimates in Gojam of 2.4% based on market counts by Oomen [20] and 2.3% based on school enquiry by Price [21] nearly four decades ago in Debre Markos, the capital of East Gojam Zone. These studies had limitations since they were based on market counts of cases and school enquiry of students from villages and were therefore likely to underestimate the overall prevalence. Nevertheless, the absence of decline in prevalence of podoconiosis after four decades clearly reflects that podoconiosis has remained neglected in the Amhara region.

Based on our findings, we reviewed the potential opportunities and challenges for primary and secondary prevention of podoconiosis in Gojam. Primary prevention consists of avoiding prolonged skin to soil contact by wearing protective shoes and socks. Secondary prevention requires regular foot hygiene, and the use of antiseptic soaks and emollients. Early evidence of effectiveness of this treatment in reducing leg circumference and disease stage and in improving quality of life has recently emerged from a small, uncontrolled follow-up study by Sikorski et. al [9]. Since most cases of podoconiosis in the present study were in the early stages of 2 and 3, secondary prevention is potentially possible in this area.

The study also revealed several challenges to primary and secondary prevention. First, there were serious deficiencies in protection against the soil with footwear. Suboptimal shoe-wearing behavior was reported even among those owning shoes, and observation at the time of interviews confirmed a substantial proportion of barefoot respondents. The types of shoes worn by most patients were not considered protective. Although men owned more pairs of shoes than women, there were similar low levels of shoe wearing and foot washing practice among men and women resulting in almost equal prevalence of disease. However, more advanced stages were seen among women. The similar average age of onset of leg swelling and age of first shoe wearing indicate prolonged contact with the soil and delay in protection.

| Clinical stage                      | Male (n = 611) | Female (n = 572) | Overall (n = 1,183) |
|-------------------------------------|---------------|-----------------|-------------------|
| Unilateral swelling, n (%)         |               |                 |                   |
| Stage I                             | 71 (11.6)     | 37 (6.5)        | 108 (9.1)         |
| Stage II                            | 593 (97.1)    | 503 (87.9)      | 1,096 (92.6)      |
| Bilateral and symmetric swelling, n (%) |           |                 |                   |

Figure 1. Clinical stages of podoconiosis among female and male patients in Debre Eliyas and Dembecha woredas, northern Ethiopia.

doi:10.1371/journal.pntd.0001744.g001
Secondly, there was substantial continuous contact with irritant soil. In addition to daily work as subsistence farmers, the frequency of travel and walking distances to and from water sources, markets and fields considerably increased the duration of contact with the soil. Limited access to water (average round trip of 40 minutes) may explain poor foot hygiene as patients prioritize water for drinking and cooking before washing their feet. The average time spent travelling to get water in Gojam was greater than in Gulliso, western Ethiopia (average round trip of 20 minutes) and also greater than the WHO recommended maximum (30 minutes round trip) [25]. This will constitute a considerable challenge for primary and secondary prevention of podoconiosis in Gojam.

Thirdly, the long interval between onset of swelling and seeking treatment indicate an important delay in accessing secondary prevention to control disease progression. Most of the podoconiosis cases in our study were found in the highland areas away from the towns where most health centers are based. There was no podoconiosis treatment in Amhara Region before the establishment of the IOCC podoconiosis prevention and treatment center in June 2010. The patients who visited health centers for treatment may not have received appropriate treatment, forcing them to try other forms of support including traditional medicine. Previous studies have demonstrated health professionals’ misconceptions surrounding podoconiosis and stigmatizing attitudes towards patients, so patients who attended formal health facilities may not have received treatment [26].

Fourthly, limited knowledge and misconceptions about the disease by the patients themselves may also act as a barrier against primary and secondary prevention by delaying treatment seeking behavior [27]. In Wolaita, adopting avoidant coping strategies led to patient isolation and reduced access to health care [28]. Similarly, linking ALA to a range of experiences including mitch resulted in poor treatment seeking and resorting to traditional medicine for a significant proportion of the patients.

This study reinforces recent evidence from Gulliso indicating the enormous burden imposed by ALA among podoconiosis patients [19]. The frequency of attacks, duration of pain and number of bed days due to ALA were all considerable. Physical examination of the interviewees reporting ALA at the time of interview confirmed the widespread frequency of the problem. Although our study did not compare the financial status of patients with unaffected people in the area, previous studies have shown the large economic burden imposed by podoconiosis [25]. This burden arises because of the concentration of the disease in the productive age group as seen in this study and the effect of ALA hampering productivity [10,29].

In conclusion, the prevalence of podoconiosis in Gojam is almost identical to that described in the 1970s by Price and

| Feature                                      | Category               | Male        | Female       | Overall     |

Table 4. Features of acute lymphadenitis (ALA) in podoconiosis patients.
Ooman [20,21] indicating that the disease has been almost entirely neglected since that time. Significant challenges remain in increasing protective shoe-wearing practices, improving access to water for washing, and encouraging earlier treatment seeking. However, given that early stages of disease were predominantly observed, if treatment is offered, it is likely to be effective.

Acknowledgments
The authors would like to thank the Zonal and Woreda Health Offices of East and West Gojam for coordinating the study. We also thank the nurses and health extension workers who collected data, the data clerks that entered the data, Mr Tekleselassie Gelane who translated the questionnaire from English to Amharic, Dr Fasil Tekola Ayele who provided expert advice on the design of the study, and all study participants.

Author Contributions
Conceived and designed the experiments: YBM ST TA AT GD. Performed the experiments: YBM ST TA AT. Analyzed the data: YBM. Contributed reagents/materials/analysis tools: YBM. Wrote the paper: YBM ST GD.
