Learning Selective Sensor Fusion for State Estimation

Changhao Chen, Member, IEEE, Stefano Rosa, Chris Xiaoxuan Lu, Bing Wang, Niki Trigoni, and Andrew Markham

Abstract—Autonomous vehicles and mobile robotic systems are typically equipped with multiple sensors to provide redundancy. By integrating the observations from different sensors, these mobile agents are able to perceive the environment and estimate system states, e.g., locations and orientations. Although deep learning (DL) approaches to multimodal odometry estimation and localization have gained traction, they rarely focus on the issue of robust sensor fusion—a necessary consideration to deal with noisy or incomplete sensor observations in the real world. Moreover, current deep odometry models suffer from a lack of interpretability. To this extent, we propose SelectFusion, an end-to-end selective sensor fusion module that can be applied to useful pairs of sensor modalities, such as monocular images and inertial measurements, depth images, and light detection and ranging (LIDAR) point clouds. Our model is a uniform framework that is not restricted to specific modality or task. During prediction, the network is able to assess the reliability of the latent features from different sensor modalities and to estimate trajectory at both scale and global pose. In particular, we propose two fusion modules—a deterministic soft fusion and a stochastic hard fusion—and offer a comprehensive study of the new strategies compared with trivial direct fusion. We extensively evaluate all fusion strategies both on public datasets and on progressively degraded datasets that present synthetic occlusions, noisy and missing data, and time misalignment between sensors, and we investigate the effectiveness of the different fusion strategies in attending the most reliable features, which in itself provides insights into the operation of the various models.

Index Terms—Deep neural networks (DNNs), feature selection, localization, multimodal learning, point cloud odometry, robot navigation, sensor fusion, visual-inertial odometry (VIO).

I. INTRODUCTION

Mobile agents are often outfitted with multiple sensors. For example, a self-driving vehicle is equipped with a combination of GPS, inertial measurement units (IMUs), cameras, and light detection and ranging (LIDAR). Making such mobile agents fully autonomous and intelligent requires the ability of sensor fusion, a method that can effectively exploit the individual strengths of distinct sensors and coherently estimate the system states. Multimodal sensor fusion has long been a central problem in robotics and computer vision [41], with applications to perception, planning, and control. Despite different application scenarios, the rationale for sensor fusion is more or less the same: many system state variables are not always fully observable by a single sensor modality, and combining different sensors that are complementary to each other can reduce the overall uncertainty, improving accuracy and/or robustness. Conventional sensor fusion methods resort to handcrafted design that heavily relies on human experience and domain knowledge. Consequently, the developed fusion methods are often modality-specific and/or task-specific.

Recently, there are growing interests in applying deep neural networks (DNNs) for learning to estimate system states in an end-to-end manner, for example, solving visual odometry (VO) [20], [45], [53], visual-inertial odometry (VIO) [7], [35], or camera relocalization [6], [22]. Instead of building analytical models by hand, they are achieved by learning complex mapping functions directly from raw sensory data to target values. These end-to-end approaches are appealing due to the capability of deep networks to automatically extract features from high-dimensional raw data. However, despite the long history of classical sensor fusion techniques, there is a lack of effective fusion strategies working on the deep feature space, especially for the tasks of localization and odometry estimation. These previous learning-based methods are not explicitly modeling error sources in real-world usage. Without considering possible sensor errors, all features are directly fed into other modules for further pose regression in [1], [6], and [22], or simply concatenated as in [7]. These factors can possibly cause troubles to the accuracy and safety of neural systems, when input data are corrupted or missing. Moreover, the features from different modalities are considered equally important in these methods, although the complementary property of different modalities requires systems to utilize...
deep features with regard to observation uncertainties or self-/environmental dynamics.

For this reason, we present a generic framework that models feature selection for robust sensor fusion, as illustrated in Fig. 1. This work mainly considers the problem of using a pair of sensor modalities, although it can be extended naturally to three or more modalities. As a case study, two tasks—learning global localization and ego-motion estimation—are chosen to demonstrate the effectiveness of our proposed selective sensor fusion. Our system is not restricted to specific modality, performing feature selection from four different sensor data, i.e., RGB images, inertial measurements, LIDAR point clouds, and depth images. The selection process is conditioned on the measurement reliability and the dynamics of both self-motion and environment. Two alternative feature-weighting strategies are presented: soft fusion, implemented in a deterministic fashion; and hard fusion, which introduces stochastic noise and intuitively learns to keep the most relevant feature representations, while discarding useless or misleading information.

By explicitly modeling the selection process, we are able to demonstrate the strong correlation between selected features and environmental/measurement dynamics by visualizing the sensor fusion masks, as illustrated in Fig. 9. In the case of estimating VIO, our results show that features extracted from different modalities (i.e., vision and inertial motion) are complementary in various conditions: inertial features contribute more in the presence of fast rotation, while visual features are preferred during large translations (see Fig. 11). Thus, the selective sensor fusion provides insights into the underlying strengths of each sensor modality, guiding the future multimodal system design. We demonstrate how incorporating selective sensor fusion makes neural models robust to data corruption typically encountered in real-world scenarios.

This article builds on the work published in [4], and presents a generic framework for selective sensor fusion in multimodal deep pose estimation. This work extends the fusion strategies from VIO to the problem of learning LIDAR-VO and RGB-depth relocalization. To summarize, the novel contributions of this work are as follows.

1) We present SelectFusion, a novel generic framework to learn selective sensor fusion enabling more robust and accurate odometry and localization in real-world scenarios.

2) We show how our selective sensor fusion can be incorporated into a uniform framework, not restricted by specific modality or task, by learning odometry estimation or relocalization on fusing a pair of modalities from vision, depth, inertial, and LIDAR data.

3) Our SelectFusion masks can be visualized and interpreted, providing deeper insights into the relative strengths of each stream, and guiding future system design.

4) We create challenging datasets on top of current public datasets by considering seven different sources of sensor degradation, and conduct a new and complete study on the accuracy and robustness of deep sensor fusion in the presence of corrupted data.

The reminder of the article is organized as follows. Section II contains a survey of related work. Section III presents a generic framework for multimodal sensor fusion. Section IV introduces our proposed selective sensor fusion mechanism. Section V evaluates SelectFusion applied to three multimodal models for relocalization and trajectory estimation through extensive experiments. Section VI finally draws conclusions.

II. BACKGROUND AND RELATED WORK

A. Learning-Based Pose Estimation

1) Visual-Inertial Odometry: Recent work shows how it is possible to learn to estimate odometry from inertial data using recurrent neural networks [3], making deep VIO estimation possible. ViNet [22] uses neural network to learn VIO, by directly concatenating visual and inertial features. VIO Learner [35] presents an online error correction module for deep VIO that estimates the trajectory by fusing RGB-D images with inertial data. DeepVIO [15] recently proposes a fusion network to fuse visual and inertial features. This network is trained with a dedicated loss. However, this way of learning sensor fusion does not expose the behavior of the fusion module, while we propose the use of an interpretable mask that offers insight into the usefulness of the input at any time. We observe that previous methods do not properly address the problem of learning a meaningful sensor fusion strategy, but it simply concatenates visual and inertial features in latent space.

2) LIDAR Odometry: Learning LIDAR odometry has been explored by LO-Net [26], which exploits geometric consistency for scan-to-scan motion estimation, while also learning pose correction similar to deep simultaneous localization and mapping (SLAM) approaches, and can achieve accuracy comparable to traditional approaches [29]. Fusion of LIDAR and visual information has been investigated in [13], which proposes to fuse LIDAR and visual information, but in their work, the learning is limited to training a model for removal of moving objects rather than localization.

3) Camera Relocalization: Deep approaches have also been devoted to visual localization. PoseNet [22] is the first work to use convolutional neural networks (CNNs) for 6-DOF pose regression from monocular images. PoseNet has been further improved by combining CNNs and long short-term memories (LSTMs) for feature correlation [43], introducing temporal
Multimodal learning aims to solve machine-learning problems involving multiple data modalities. They are generally categorized into aggregation-based and alignment-based fusion methods. The success of multimodal learning has been demonstrated in a wide range of applications, e.g., video captioning [39], medical image retrieval [14], face recognition [8], manipulation [23], autonomous navigation [27], and body-sensor networks [44]. Recently, [46] designs a channel-exchanging network (CEN) that fuses multiple modalities by dynamically exchanging the channels of subnetworks. Li et al. [25] propose a residual fusion network (RFN)-based framework that automatically extracts features and fuses multiscale features. In [38] and [40], a shared layer is designed to transfer cross-modal features, in which an inner product function of extracted features from two modalities is adopted to combine them for domain transferring. This inner product method is similar to our soft fusion but for different purposes. However, there is a lack of systematic study into the sensor fusion for deep state estimation, especially in learning-based localization and pose estimation, as discussed in Section II-A.

C. Attention Mechanism

Our proposed selective sensor fusion is particularly related to attention mechanisms that have been widely applied in neural machine translation [10], image caption generation [48], visual question answering [28], and video description [17]. Limited by the fixed-length vector in embedding space, these attention mechanisms compute a focus map to help the decoder, when generating a sequence of words. This is different from our design intention that the feature selection works to fuse multimodal sensor fusion for deep pose estimation, and cope with more complex error resources and self-motion dynamics.

III. LEARNING MULTIMODAL REPRESENTATIONS

This section presents a uniform framework to learn multimodal representation for state estimation, which lays the foundation for selective sensor fusion. Figs. 2–4 show a modular overview of the architecture, consisting of feature encoders, feature fusion, temporal modeling, and task solver.

A. Feature Encoders

1) Visual Feature Encoders: As visual feature encoders are used in both global relocalization and odometry estimation, they are designed with respect to the property of each task for better feature extraction and utilization.

For a relative pose (odometry) estimation, latent representations are extracted from a set of two consecutive monocular images \( x_v \). Ideally, we want our visual encoder \( f_v \) to learn geometrically meaningful features rather than features overfitted with appearance or context. For this reason, instead of using a PoseNet model [22], as commonly found in other DL-based VO approaches [50], [51], [53], we use a FlowNet-style architecture, i.e., FlowNetSimple [9] as our feature encoder. Flownet provides features that are suited for optical flow prediction, which highly contributes to the ego-motion detection. The network consists of nine convolutional layers. The size of the receptive fields gradually reduces from \( 7 \times 7 \) to \( 5 \times 5 \) and finally to \( 3 \times 3 \), with stride two for the first six layers. Each layer is followed by a ReLU nonlinearity except for the last one, and we use the features from the last convolutional layer \( a_v \) as our visual feature. We initialize the visual encoder with the weights of a model that was pretrained on the FlyingChairs dataset, since training from scratch would require a larger amount of data compared with our dataset size.

For a global relocalization task, we instead use residual neural network (ResNet) [16] to extract features from a set of single images. Both structure and appearance features contribute to the retrieval of absolute poses in the 3-D scene that has been visited before. Hence, visual features should capture the entire scene. We adopt ResNet18, consisting of 18 convolutional layers with skip connections, and modify it by introducing an average pooling layer and a full-connected layer at the end, which transform the features after ResNet18 to a \( d \)-dimensional visual feature \( a_v \).

In summary, given a set of images \( x_v \), we are able to extract visual features \( a_v \in \mathbb{R}^d \) suited to the task via the visual encoder (FlowNet) or (ResNet) \( f_v \):

\[
a_v = f_v(x_v). \tag{1}
\]

2) Inertial Feature Encoder: Inertial data streams have a strong temporal component, and are generally available at higher frequency (\( \sim 100 \) Hz) than images (\( \sim 10 \) Hz). In order to model the temporal dependences of consecutive inertial measurements, we use a two-layer bidirectional LSTM with 128 hidden states as the inertial feature encoder \( f_{\text{inertial}} \). In the deep VIO model, as shown in Fig. 4, a window of inertial measurements \( x_i \) between each two images is fed to the inertial feature encoder in order to extract the \( d \)-dimensional feature vector \( a_i \in \mathbb{R}^d \): \n
\[
a_i = f_{\text{inertial}}(x_i). \tag{2}
\]

3) Depth Feature Encoder: In our work, depth image is exploited to solve the task of vision-depth-based relocalization, as shown in Fig. 2. Similar to the visual encoder designed for relocalization, we also use ResNet18 as depth feature encoder but replace the first layer of ResNet model with a one-channel convolutional network, considering that depth image is one channel rather than three channels. Hence, the input is a set of one-channel depth images \( x_d \), and transformed into a \( d \)-dimensional feature vector \( a_d \in \mathbb{R}^d \) via the depth encoder \( f_d \):

\[
a_d = f_d(x_d). \tag{3}
\]

Fig. 3. Overview of our neural LIDAR-VO (Task 2) architecture with proposed selective sensor fusion, consisting of visual and LIDAR encoders, feature fusion, temporal modeling, and task solver (relative pose regression).

Fig. 4. Overview of our neural VIO (Task 3) architecture with proposed selective sensor fusion, consisting of visual and inertial encoders, feature fusion, temporal modeling, and task solver (relative pose regression).

4) Pointcloud Feature Encoder: The point clouds are a set of data in Cartesian coordinates, representing 3-D structure in space. They are produced normally by LIDAR devices. The sparse structure and irregular format of point cloud data...
make them hard to be processed directly by neural networks. To allow CNNs to effectively process point cloud data, we convert them into a regular point cloud matrix via the cylindrical projection \[ \alpha = \arctan(y/x) / \Delta \alpha \] \[ \beta = \arcsin(z/\sqrt{x^2 + y^2 + z^2}) / \Delta \beta \] where \((x, y, z)\) are original coordinates in the LIDAR coordinate system, and \((\alpha, \beta)\) are new coordinates in the point cloud matrix. The new point cloud matrix is with a size of \(H \times W \times C\). The position \((\alpha, \beta)\) of matrix is filled with the range value \(r = (x^2 + y^2 + z^2)^{1/2}\) from the position \((x, y, z)\) of original point cloud.

In this work, point cloud data are used to learn vision-LIDAR odometry, as shown in Fig. 3, and hence, we also use the FlowNet visual encoder to transform the input matrix \(x_P\) into a \(d\)-dimensional point cloud feature \(a_P \in \mathbb{R}^d\)

\[
a_P = f_{\text{pointcloud}}(x_P). \tag{6} \]

\[ a_P = f_{\text{pointcloud}}(x_P). \tag{6} \]

B. Fusion Function

We now combine the high-level representation produced by each feature encoder from raw data sequences, with a fusion function \(g\) that combines information from a pair of sensor modalities to extract the useful combined feature \(z\) for a regression task

\[
z = g(a_1, a_2) \tag{7} \]

where \((a_1, a_2)\) is any pair of sensor modality features from visual \(a_V\), inertial \(a_I\), depth \(a_D\), and point cloud \(a_P\) channels. In this work, we specifically investigate the problem of fusing two sensor modalities for better demonstration on existing datasets, although our framework can extend naturally to exploit three or more modalities.

There are several different ways to implement this fusion function, as shown in Fig. 5. The current approach is to directly concatenate the two features together into one feature space (we call this method as direct fusion \(g_{\text{direct}}\)). However, in order to learn a robust sensor fusion model, we propose two fusion schemes—deterministic soft fusion \(g_{\text{soft}}\) and stochastic hard fusion \(g_{\text{hard}}\)—which explicitly model the feature selection process according to the current environment dynamics and the reliability of the data input. The fusion network is another DNN module. Details will be discussed in Section IV.

C. Temporal Modeling and Task Solvers

The fundamental tenet of state estimation requires modeling temporal dependences to derive accurate system states, e.g., relative poses. In the past, a state-space model (SSM) describes this temporal relation and evolution of system states. Similarly, in our learning model, a recurrent neural network, i.e., LSTM network takes in the input combined feature representation \(z\) at time step \(t\) and its previous hidden states \(h_{t-1}\) and models the dynamics and connections between a sequence of features. The hidden states \(h_t\) contain the history of the features relevant to the task. After the recurrent network, a fully connected layer serves as the regressor, transforming the features to a system state \(y_t\), i.e., pose transformation or global pose, representing the motion transformation over a time window or a global location/orientation.

Hence, the relation between the final system states \(y_t\) and the input features \(z_t\) can be described via a recurrent neural network and previous hidden states \(h_{t-1}\)

\[
y_t = \text{RNN}(z_t, h_{t-1}). \tag{8} \]

We implemented three tasks based on this multimodal representation learning framework to estimate key system states from pairs of raw sensory data.

1) Task 1 Learning Vision-Depth Relocalization: The first task is to exploit monocular RGB images and depth images to perform global relocalization in the scenarios that have been visited before. As illustrated in Fig 2, depth and RGB images are encoded into features by the depth encoder and visual encoder (ResNet), fused as new features through feature fusion modules, and converted into global poses via temporal modeling and task regression modules. The global pose \(y = [p, q]\) is composed of a 3-D position vector \(p \in \mathbb{R}^3\) and a quaternion \(q \in \mathbb{R}^4\) for orientation. The objective is to minimize the \(L1\) distance between the groundtruth values \([\hat{p}, \hat{q}]\) and predicted values \([p, q]\) with the loss function

\[
L(\theta) = |\hat{p} - p| + \lambda_1 |\hat{q} - q| / ||q|| \tag{9} \]

where \(\lambda_1\) is a balance factor, which we choose as \(\lambda_1 = 10\) in our experiment. Here, \(L1\) loss is chosen rather than \(L2\) loss, because \(L1\) loss performs better and more stable [21].

Fig. 5. Overview of three fusion methods. (a) Direct fusion. (b) Soft fusion. (c) Hard fusion.
2) Task 2 Learning LIDAR-Vision Odometry: The second task is to learn LIDAR-vision odometry. Different from global relocalization, odometry estimation produces relative poses between two frames of images, which can adapt to new scenarios. Global pose is achieved by integrating pose transformations. As shown in Fig. 3, the framework consists of point cloud encoder and visual encoder (FlowNet) that extract features from LIDAR point cloud data and RGB images, feature fusion that combines LIDAR and visual features as a new feature vector, and temporal modeling and task solver modules to transform features as system states. The network outputs relative poses $y = [p, r]$, consisting of a 3-D translation vector $p \in \mathbb{R}^3$, and a 3-D Euler rotation vector $r \in \mathbb{R}^3$. The objective is to minimize the mean square error (mse) of the relative poses to recover optimal neural network parameters $\theta$.

$$L(\theta)_2 = ||\hat{p} - p||_2 + \lambda_2 ||\hat{r} - r||_2$$

(10)

where $[\hat{p}, \hat{r}]$ are groundtruth values, and $\lambda_2$ is a scale factor to balance between translational error and rotational error. $\lambda_2$ is chosen as 100 in our experiment.

3) Task 3 Learning VIO: The third task is to learn VIO, providing accurate pose estimation by using visual and inertial sensors, which are widely deployed in mobile robotics, self-driving vehicles, and drones. Similar to LIDAR-vision odometry, our model outputs the relative poses between two frames of images. Fig. 4 shows that visual and inertial features are extracted from consecutive monocular images, and a sequence of inertial data between two frames of images by FlowNet-based visual encoder and LSTM-based inertial encoder. The features are combined as new features via feature fusion, and converted into system states through temporal modeling and task regressor. The network produces pose transformation $y = [p, r]$ with a 3-D translation vector $p \in \mathbb{R}^3$, and a 3-D rotation vector $r \in \mathbb{R}^3$ (the rotation vector is represented by 3-D Euler angles). By minimizing the mse of the predicted relative poses, the optimal parameters $\theta$ are recovered via

$$L(\theta)_3 = ||\hat{p} - p||_2 + \lambda_3 ||\hat{r} - r||_2$$

(11)

where $[\hat{p}, \hat{r}]$ are true relative poses, $[p, r]$ are predicted values, and $\lambda_3$ is a scale factor to balance between translational error and rotational error. In our case, we choose $\lambda_3$ as 100.

IV. SELECTIVE SENSOR FUSION

In this section, we propose SelectFusion, a generic framework to selectively learn multisensory representation from raw data. Intuitively, the features from each modality offer different strengths for the task of state estimation. Our perspective is that simply considering all features as they are equally important and correct, without any consideration of degradation and self/environmental dynamics, is unwise and will lead to unrecoverable drifts and errors. Therefore, we propose two different selective sensor fusion schemes for explicitly learning the feature selection process: soft (deterministic) fusion, and hard (stochastic) fusion, as illustrated in Fig. 6. In addition, we also present a straightforward sensor fusion scheme—direct fusion—as a baseline model for comparison.

A. Direct Fusion

A straightforward approach for implementing sensor fusion consists in the use of multilayer perceptrons (MLPs) to combine the features from the two sensor modality channels. Ideally, the system learns to discriminate relevant features for prediction in an end-to-end fashion. Hence, direct fusion is modeled as

$$g_{\text{direct}}(\mathbf{a}_1; \mathbf{a}_2) = [\mathbf{a}_1; \mathbf{a}_2]$$

(12)

where $[\mathbf{a}_1; \mathbf{a}_2]$ denotes an operation function that concatenates features $\mathbf{a}_1$ and $\mathbf{a}_2$, which are extracted from the Modalities 1 and 2, respectively.

B. Soft Fusion (Deterministic)

We now propose a soft fusion scheme that explicitly and deterministically models feature selection. Similar to the widely applied attention mechanism [17], [42], [48], this function reweights each feature by conditioning on both sensor modality channels, allowing the feature selection process to be jointly trained with other modules. The function is deterministic and differentiable.

Here, a pair of continuous masks $s_1$ and $s_2$ are introduced to implement soft selection of the extracted feature representations, before these features are passed to temporal modeling and task solver.

$$s_1 = \text{Sigmoid}(\text{MLP}_1([\mathbf{a}_1; \mathbf{a}_2]))$$

(13)

$$s_2 = \text{Sigmoid}(\text{MLP}_2([\mathbf{a}_1; \mathbf{a}_2]))$$

(14)

where $[\mathbf{a}_1; \mathbf{a}_2]$ denotes an operation function that concatenates features $\mathbf{a}_1$ and $\mathbf{a}_2$. MLP is a feedforward neural network that transforms features to fusion mask space. The Sigmoid function makes sure that each of the features will be reweighted in the range $[0, 1]$. This process is deterministically parameterized by the neural networks, conditioned on both the features $\mathbf{a}_1$ and features $\mathbf{a}_2$. $s_1$ and $s_2$ represent soft masks applied to the features extracted from modalities 1 and 2, respectively.
Then, the visual and inertial features are elementwise multiplied with their corresponding soft masks as the new reweighted vectors. The selective soft fusion function is modeled as
\[ g_{\text{soft}}(\mathbf{a}_1, \mathbf{a}_2) = [\mathbf{a}_1 \odot \mathbf{s}_1; \mathbf{a}_2 \odot \mathbf{s}_2]. \quad (15) \]

C. Hard Fusion (Stochastic)

In addition to the soft fusion introduced earlier, we propose a variant of the fusion scheme—hard fusion. Instead of reweighting each feature with a continuous value, hard fusion learns a stochastic function that generates a binary mask that either propagates the feature or blocks it. This mechanism can be viewed as a switcher for each component of the feature map, which is a stochastic layer implemented by a parametrized Bernoulli distributions.

However, the stochastic layer cannot be trained directly by back-propagation, as gradients will not propagate through discrete latent variables. To tackle this, the REINFORCE algorithm [32], [47] is generally used to construct the gradient estimator. In our case, we propose to employ a more lightweight method—Gumbel-Softmax resampling [19], [30] to infer the stochastic layer of hard fusion, so that our hard fusion module can be trained in an end-to-end fashion as well.

Before training the model, the distribution of hard mask is unknown. As each element of this mask consists of the value 0 with probability \( p \) and the value 0 with probability \( q = 1 - p \). As the entire mask \( s \) consists of \( n \) elements, it is under the binomial distribution with parameters \( n \), which is the discrete probability distribution of the number of successes in a sequence of \( n \) independent experiments. Therefore, instead of learning masks deterministically from features, hard masks \( s_1 \) and \( s_2 \), representing the binary mask for the features from two modalities, are resampled from a discrete Binomial distribution. This discrete distribution is parameterized by \( \alpha \), which is learned by DNNs and conditioned on features but with the addition of stochastic noise
\[
\begin{align*}
\mathbf{s}_1 &\sim \text{Binomial}(\alpha) \quad (16) \\
\mathbf{s}_2 &\sim \text{Binomial}(\alpha) \quad (17)
\end{align*}
\]
where each mask \( s = [s^{(1)}; \ldots; s^{(n)}] \) is an \( n \)-dimensional binary vector \( s^{(i)} \). Each element of hard mask \( s^{(i)} \) is a 2-D categorical variable, deciding whether to select the \( i \)th feature or not. The total number of features is \( n \). The element \( s^{(i)} \) can be viewed as resampling from a Bernoulli distribution
\[ s^{(i)} \sim \text{Bernoulli}(\alpha^{(i)}). \quad (18) \]

Similar to soft fusion, the features from two modalities are elementwise multiplied with their corresponding hard masks as new reweighted vectors. The stochastic hard fusion function is modeled as
\[ g_{\text{hard}}(\mathbf{a}_1, \mathbf{a}_2) = [\mathbf{a}_1 \odot \mathbf{s}_1; \mathbf{a}_2 \odot \mathbf{s}_2]. \quad (19) \]

Now, we come to solve the problem of inferring this discrete distribution in order to generate hard mask \( s \). We apply the so-called Gumbel-Softmax trick to convert the noncontinuous function into a continuous approximation by using the fact that the distribution of a discrete random variable \( P(x = k) \) can be reparameterized by a random variable \( \pi_k \) and a Gumbel random variable \( \epsilon_k \) via
\[ x = \arg \max_k (\log \pi_k + \epsilon_k). \quad (20) \]

In practical, it is simple to implement this reparameterization trick into our model. Fig. 6(b) shows the detailed workflow of our proposed Gumbel-Softmax resampling-based hard fusion. The Gumbel-max trick [31] allows us to efficiently draw a hard mask \( s^{(i)} \) from a categorical distribution given the class vector \( \pi_k^{(i)} \) and a Gumbel random variable \( \epsilon_k^{(i)} \), and then, a one-hot encoding performs “binarization” of the category
\[ s^{(i)} = \text{one
hot}(\arg \max_k (\epsilon_k^{(i)} + \log \pi_k^{(i)})) \quad (21) \]
where \( i \in [1, \ldots, n] \) is the index of feature, and \( k \in [1, 2] \) is the index of class vector for each feature. In this case, there are only two categories, indicating whether to select a particular feature or not. This can be viewed as a process of adding independent Gumbel perturbations to the discrete class variable. In practice, the random variable \( \epsilon \) is sampled from a Gumbel distribution, which is a continuous distribution on the simplex that can approximate categorical samples
\[ \epsilon = -\log(-\log(u)), u \sim \text{Uniform}(0, 1). \quad (22) \]

In (21), the argmax operation is not differentiable, so softmax function is used as an approximation
\[ h^{(i)} = \frac{\exp((\log(\pi_k^{(i)}) + \epsilon_k^{(i)})/\tau)}{\sum_{j=1}^2 \exp((\log(\pi_j^{(i)}) + \epsilon_j^{(i)})/\tau)}, k = 1, 2 \quad (23) \]
where \( \tau > 0 \) is the temperature that modulates the re-sampling process. Finally, \( h^{(i)} \) is transformed into a binary mask \( s^{(i)} \) through the one_hot function.

The \( \pi_k^{(i)} \) is jointly learned by DNNs in our models, and formulated as the parameters \( \alpha = (\pi_k^{(i)})_{k=1}^n \), conditioned on the concatenated feature vectors \([\mathbf{a}_1; \mathbf{a}_2]\) from two modalities
\[ \alpha = \text{ReLU}(\text{FC}([\mathbf{a}_1; \mathbf{a}_2])) \quad (24) \]
where FC is fully connected layer, to map concatenated features into \( k \times 2 \) dimension class vectors. ReLU is to impose nonlinearity and ensures the class vectors to be nonnegative.

In our approach, we find that modulating the temperature with respect to the training procedure can enable a better performance in selective sensor fusion. This is because the temperature determines the samples and gradients: when the temperature is high, the variance of the gradients is small, while the samples are more smooth; at low temperatures, the variance of the gradients is high, while the samples are more discrete, which means that it will fit well into the discrete distribution of the fusion mask. Thus, we start the temperature from a higher value, i.e., 1 in our case, and gradually decrease it toward 0.5 over each epoch of the training process.
V. EXPERIMENTS

We conducted extensive experiments on four well-known public datasets to learn from different pairs of sensor modalities: the 7-Scenes dataset [37] for vision-depth-based relocalization (Task 1), the KITTI odometry dataset [11] for vision-LIDAR odometry estimation (Task 2), and the KITTI raw dataset [11] and the EuRoC MAV dataset [2] for VIO (Task 3).

A. Experimental Setups

Our frameworks were implemented with PyTorch and trained on a NVIDIA Titan X GPU. As the main focus of this work is a study of the general multimodal fusion problem, we want to investigate the performance of the two SelectFusion strategies compared with preexisting models. In each task, we always choose a deep vision-only model and a deep multimodal model with direct fusion as the common baselines. Additionally, specific representative works were chosen as task baselines, according to each specific task. All of our networks including common baselines were trained with a batch size of 16 using the Adam optimizer, with a learning rate \( lr = 1e^{-4} \), for a fair comparison. All models were trained for 100 epochs, and the sequence length is chosen as 5.

1) Common Baselines: Common baselines share the same basic framework as our proposed SelectFusion framework. For a fair comparison, the hyperparameters of proposed network and common baselines are identical, including batch size, learning rate, and the dimension of hidden states. The vision-only model is composed of the same visual encoder, temporal modeling, and task solver modules as our framework. The multimodal model with direct fusion uses the same structure as our proposed framework, except for the fusion component, which is a simple concatenation of the multimodal features. The single modality model and multimodal model with direct fusion can be viewed as ablated variants of our proposed approach. In addition, we also compare with a recent multimodal fusion work, i.e., RFN [25], which is based on the nest connection incorporated into a ResNet. In the task of depth-vision relocalization and LIDAR-vision odometry, RFN is employed into a framework with the same feature extractors as our select fusion for a fair comparison, but fusion module is replaced with the residual network that aggregates and fuses the features from each extractor. RFN is not employed in VIO, as inertial data are processed with an LSTM, which is not suitable to this CNN-based RFN.

2) Vision-Depth Relocalization:

a) 7-Scenes Dataset (Vision + Depth): The 7-Scenes dataset [37] contains RGB images and depth data captured by a handheld Microsoft Kinect camera from seven indoor scenarios. Each scene provides several sequences, and each sequence is with 500–1000 frames of color and depth images. We follow the official data split to train and test our models on this dataset.

b) Task Baselines: Our SelectFusion model is built as an end-to-end relocalization model, and thus, we compare with LSTM-Pose [43], VidLoc [6], and MS-Transformer [36], which are representative within this category of learning techniques.

c) Task Baselines: We choose four representative VIO pipelines, i.e., MSCKF [18], OKVIS [24], mono-VINS [34], and VIOlearner [35] as task baselines to compare with our deep VIOs: MSCKF [18] is an extended Kalman filter-based solution; OKVIS [24] is a keyframe-based VIO with sliding window nonlinear optimization; mono-VINS [34] uses sliding window nonlinear optimization and IMU preintegration. VIOlearner [35] is a learning-based VIO with online error correction.

B. Runtime and Parameter Sensitivity

This section analyzes the runtime and parameter sensitivity of our proposed fusion mechanisms.

We first test direct fusion, soft fusion, and hard fusion in the task of learning VIO, to collect their prediction time on a NVIDIA RTX 3080Ti GPU and an Intel Xeon 2.4-GHz CPU. Fig. 7 reports the averaged results over the per-frame testing time on Sequence 05 of the KITTI dataset. It is clear to see
TABLE I

- For a fair comparison, the bold character highlights the best results among our proposed approaches and common baselines, excluding task baselines.

that no matter our soft fusion or hard fusion only increases the computation burden slightly, compared with direct fusion. For hard fusion model, the runtime of each prediction is 12.76 and 63.15 ms on a GPU and a CPU, respectively. Thus, it can achieve 78 frames/s on a GPU and 15 frames/s on a CPU, which would satisfy the real-time requirement of most robotic applications.

One of the main hyperparameters inside SelectFusion and baseline frameworks is the feature dimension of fusion module. It determines the dimension of extracted features in the feature extractors and the dimension of hidden states in the recurrent neural networks. To study the influence of this hyperparameter, we test hard fusion model in the task of VIO with five different feature dimensions from 32 to 1024. Fig. 8 shows a comparison of the validation losses in terms of training epochs. Clearly, when increasing the feature dimension from 32 to 128, the validation loss is reduced dramatically. Furthermore, the validation loss decreases slightly, when augmenting the feature dimension to 256 and 512. There is no clear change on validation loss if the feature dim is selected as 1024. Considering both model performance and memory storage, we thus use 512 as the feature dimension of fusion module in the following experiments.

C. Task 1: Global Relocalization Using Vision and Depth

We first employ selective sensor fusion to combine visual and depth information for a global localization task in indoor scenarios. The features are extracted from RGB and depth images using the visual and depth feature encoders discussed in Section III. Our models, including the common baseline (direct fusion), are trained and evaluated on the 7-Scenes dataset. For each scene, we follow the official data split to train and test our models, and report for each model the median position and orientation error, according to the convention of prior works [1], [6], [22], [43].

Table I shows the results of the common baseline (direct fusion) and our proposed SelectFusion frameworks, i.e., soft fusion [Soft (Ours)] and hard fusion [Hard (Ours)]. For a fair comparison, the only difference in three models is the feature fusion part. Clearly, our proposed SelectFusion strategies outperform the common baselines, i.e., direct fusion and RFN. In particular, hard fusion further improves the performance of the direct fusion with a gain of 8.33% in the position and 2.65% in the orientation. Although RFN performs best in the Heads scene and achieves most accurate orientation prediction in the Stairs scene, other fusion mechanisms still outperform it in the other scenes and averaged results. This shows the effectiveness of SelectFusion in learning multimodal representation for global relocalization.

In addition to the common baselines, we also choose three representative visual localization approaches as task baselines, i.e., LSTM-Pose [43], VidLoc [6], and MS-Transformer [36]. VidLoc can be viewed as a simple direct fusion, but it uses full-size images and different feature encoders. Our proposed hard fusion model outperforms LSTM-Pose [43] and VidLoc [6], showing that our models can achieve competitive performance over previous works using only the uniform framework and the proposed fusion strategies. Our method still cannot compete with the state-of-the-art relocalization

Authorized licensed use limited to the terms of the applicable license agreement with IEEE. Restrictions apply.
model, i.e., MS-Transformer with the transformer-based architecture. It demonstrates that the performance of our fusion model can be improved with the advances in feature encoders.

D. Task 2: Deep LIDAR-Vision Odometry

We now focus on the problem of learning LIDAR-vision odometry in a car-driving scenario. The models are trained on the KITTI Odometry dataset and tested on three new sequences, i.e., Sequences 05, 07, and 10. Then, the relative poses produced by the neural networks are integrated into global trajectories, which are further evaluated according to the official KITTI VO/SLAM evaluation metrics [11]. This metric is calculated by averaging the root mean square errors (RMSEs) of the translation and rotation for all the subsequences of lengths (100–800) m.

Table II shows the results of our deep LIDAR-vision odometry on the KITTI Odometry dataset. Vision only and LIDAR only models represent the model using only vision or LIDAR data to estimate ego-motion. Compared with them, fusing vision and LIDAR features (direct fusion) contributes to a large improvement no matter in translation or rotation. Soft (Ours) and Hard (Ours) are our frameworks with soft fusion and hard fusion. Our proposed hard fusion is capable of improving the performance over the naive fusion model (i.e., the direct fusion) about 3.0% in translation and 8.2% in orientation. RFN is able to predict the translation of Sequence 07 accurately, but its overall performance is not as good as other fusion mechanisms in this task. Note that these models are built on the same modules, except the feature fusion part for a fair comparison.

Meanwhile, three classical methods, i.e., monocular VO (VISO2_M) [12], and ELO [52] are chosen as task baselines to compare with our data-driven approaches. As we can see, the learning-based methods greatly outperform the two monocular VO algorithms, but still have a large performance gap with respect to the traditional LIDAR odometry, i.e., ELO [52]. The model-based methods are tailored to the specific VO or LIDAR odometry problem: ELO is built on scene geometry information and quite accurate with good-quality point cloud data; the VISO2_M relies on hand-crafted features and it is quite challenging to perform using high-dimensional raw images directly. In comparison, the data-driven models can automatically extract suitable features, which means that they are not restricted to a specific sensor modality or task, hence with the potential to explore a universal framework for deep state estimation.

E. Task 3: Deep VIO on UAV and Self-Driving Scenarios

Finally, we come to evaluate our proposed model on the KITTI raw dataset (self-driving scenario) and EuRoC MAV dataset (unmanned aerial vehicle (UAV) scenario) on learning VIO. These two datasets are challenging, as some real-world sensor degradations are contained in the original data: in the KITTI dataset, some IMU data are missing for a number of time steps; IMU and camera streams are not tightly time-synchronized, which causes temporal sensor degradation; there are moving vehicles which act to partially occlude the camera; also in the Euroc dataset, there is significant motion blur and camera occlusion. Except the real sensor degradations, we also generate synthetic data degradations on the public datasets to study the robustness of learning models.

1) Synthetic Data Degradation: In order to provide an extensive study of the effects of sensor data degradation and to evaluate the performances of the proposed approach, we generate a degraded dataset, as shown in Fig. 9, by adding various types of noise and occlusion to the original data, as described in the following.

a) Vision Degradation: Occlusions: We overlay a mask of dimensions 128 x 128 pixels on top of the sample images, at random locations for each sample. Occlusions can happen due to dust or dirt on the sensor or stationary objects close to the sensor.

Motion Blur: We introduce motion blur to represent the camera blur caused by fast ego-motion or fast object movements. This motion blur is generated by estimating the relative motion of the scene, and producing corresponding blur above

- For a fair comparison, the bold character highlights the best results among our proposed approaches and common baselines, excluding task baselines.

**TABLE III**

**RESULTS OF VIO (TASK 3) ON THE KITTI RAW DATASET (CAR-DRIVING SCENARIO)**

|               | Original | Vision Degrad. | All Degrad. |
|---------------|----------|----------------|-------------|
| MSCKF         | 0.48     | 30.37          | fail        |
| OKVIS         | 0.47     | 1.42           | fail        |
| mono-VINS     | 0.35     | fail           | fail        |

| Vision Only   | 2.42     | 2.44           | 1.99        |
| VIO Direct    | 0.99     | 1.14           | 1.15        |
| VIO Soft      | 1.06     | 1.18           | 1.21        |
| VIO Hard      | 0.84     | 1.04           | 1.12        |

- The results (m) are reported the root mean squared error (RMSE) of the absolute translation error (AT3).
- Vision-Only, VIO Direct, VIO Soft, and VIO Hard models are trained on the sequences except MH_05_difcult of EuRoC MAV dataset [2] and tested on Sequence MH_05_difcult.
- For a fair comparison, the bold character highlights the best results among our approaches and common baselines, excluding task baselines.
original images. Motion blur can happen when the camera or
the light condition changes substantially.

Missing Data: We randomly remove 10% of the input
images. This can occur when packets are dropped from the
bus due to excess load or temporary sensor disconnection.
It can also occur if we pass through an area of very poor
illumination, e.g., a tunnel or underpass.

b) IMU Degradation: Noise + Bias: On top of the
already noisy sensor data, we add additive white noise to the
accelerometer data and a fixed bias on the gyroscope data. This
can occur due to increased sensor temperature and mechanical
shocks, causing inevitable thermo-mechanical white noise and
random walking noise.

Missing Data: We randomly remove windows of inertial
samples between two consecutive random visual frames. This
can occur when the IMU measuring is unstable or packets are
dropped.

c) Cross-Sensor Degradation: Spatial Misalignment: We
randomly alter the relative rotation between the camera and
the IMU, compared with the initial extrinsic calibration. This
can occur due to axis misalignment and the incorrect sensor
 calibration. We uniformly model up to 10° of misalignment.

Temporal Misalignment: We apply a time shift between
windows of input images and windows of inertial measure-
ments. This can happen due to relative drifts in clocks between
independent sensor subsystems.

2) Experiment on the EuRoC Dataset: In the experiment of
EuRoC dataset, we report the root mean squared error of the
absolute translation error (ATE) of our models and baselines.
This evaluation metric is commonly adopted by previous
classical VIO works [18], [24], [34], so that our proposed
frameworks can be compared with them directly. Table III
reports the performance of learning models [i.e., Vision-Only
(DeepVO) and VIO Direct (VINet)] and classical algorithms
(i.e., MSCKF [18], OKVIS [24], and mono-VINS [34]) on
the trajectory MH_05_Difficult in the presence of normal
data, all combined visual degradation (10% occlusion, 10%
motion blur, and 10% missing data) and all combined visual +
inertial degradation (5% for each). Note that learning models
share the same framework and hyperparameters, while the
only difference is the fusion strategy. The details of data
degradations can be found in Section V-E1.

We can see that hard fusion consistently outperforms other
learning models in all three scenarios, demonstrating the
effectiveness of our proposed fusion strategy. In the normal set, hard fusion improves the direct fusion (our common baseline) by 15.15% in ATE. Another notable point is that OKVIS only shows a large performance decrease in the vision degradations, and fails on all the degradations, while mono-VINS fails on both degradation scenarios. In contrast, learning models all can work on degradation scenarios. This indicates that learning models are capable of overcoming sensor degradations to perform more robustly. Learning models still cannot compete with the classical algorithms in normal set. This is due to two reasons: 1) in the EuRoC dataset, the groundtruth values of motion tracking (from a Vicon system) and sensor data (from a UAV) are collected from two time systems, and hence, the training of learning models is limited because of the probable errors on groundtruth labels and 2) this deep VIO framework is still a basic framework, while extensions and constraints relevant to specific properties of visual and inertial sensors can be added onto it to further enhance the performance, e.g., Bundle adjustment.

3) Experiment on the KITTI Dataset: On the KITTI dataset, we use the official KITTI VO/SLAM evaluation metrics. This metric is to calculate the averaged RMSE of the translation and rotation for all the subsequences of lengths (100–800) m, which can reflect both the global and local drifts of odometry estimation.

Table IV reports the performance of our proposed hard fusion and soft fusion on the trajectories 05, 07, and 10 of normal dataset, together with two classical VIO algorithms (i.e., MCKF and VINS) and three learning models, i.e., vision only (DeepVO), VIO direct (VINet), and VIOLearner. Our proposed selective sensor fusion (hard) further improves the averaged performance of the direct fusion by 12.46% in translation and 15.98% in orientation, while soft fusion shows an improvement of 11.6% and 16.57% in translation and rotation. Due to the real issue of bad time synchronization between images and IMUs, OKVIS and mono-VINS failed on the KITTI raw dataset. We then compare with an MCKF implementation based on [18], This approach, different from OKVIS or VINS-Mono, is based on a trifocal tensor matching between triplets of successive frames, in order to get an ego-motion estimate, which is then fused with inertial information via a multistate constraint Kalman filter to refine the estimates of the camera poses for each triplet. This sliding approach arguably makes it more robust to IMU desynchronization. It is clear to see that the learning-based VIO models, including VIO (direct), VIO (soft), and VIO (hard) outperform MCKF and VINS by a large margin. This is because MCKF and VINS are limited by the bad time synchronization of two sensors, while the learning models are generally more robust to overcome such data degradations caused by real-world issues (data collection). Note that the original VIOLearner is trained on Sequences 00–08, and tested on Sequences 09 and 10 of the KITTI dataset, and thus, it is not fairly to compare with our method directly. But our VIO (hard) still outperforms VIOLearner on Sequences 07 and 10.

Tables V and VI show the performance of the proposed data fusion strategies, compared with the common baselines on the KITTI raw dataset. In particular, we compare with a DeepVO [45] (vision-only) implementation and finally with an implementation of VINE [7] (VIO Direct), which uses a naïve fusion strategy by concatenating visual and inertial features. In the vision-degraded set, the input images are randomly degraded by adding occlusion, motion blurring, and removing images, with 10% probability for each degradation. In the full degradation set, images and IMU sequences from the dataset are corrupted by all seven types of degradation with a probability of 5% each. Table V reports the results of deep VIO models in the presence of combined visual degradations, and all degradations. As we can see, our proposed selective sensor fusion, especially hard fusion, achieves a better performance than the learning models without our proposed fusion module in these sensor degradation scenarios. In each data degradation, as illustrated in Table VI, our proposed selective sensor fusion, especially hard fusion, consistently outperforms other baselines. This demonstrates to what extent our proposed SelectFusion can tolerate the perturbations of each data degradation, showing that SelectFusion is more robust to the issues caused by data degradations compared with other baselines.

- \( r_v \) is the average translational RMSE drift (% on lengths of 100m-800m.
- \( r_\theta \) is the average rotational RMSE drift (°/100m) on lengths of 100m-800m.
- The Vision-Only, VIO Direct, VIO Soft, and VIO Hard models are trained on Sequence 00, 01, 02, 04, 06, 08 and 09 of KITTI raw dataset [11] with same hyperparameters for a fair comparison, and tested on Sequence 05, 07 and 10.

Fig. 11. Task 3: Correlations between the number of inertial/visual features and amount of rotation/translation show that the inertial features contribute more with rotation rates, e.g., turning, while more visual features are selected with increasing linear velocity. (a) Inertial rotation. (b) Visual rotation. (c) Inertial translation. (d) Visual translation.

In Fig. 11, we analyze the correlation between amount of linear and angular velocity and the selected features. These results also show how the belief on inertial features is stronger in the presence of large rotations, e.g., turning, while visual features are more reliable with increasing linear translations. It is interesting to see that at low translational velocity (0.5 m/0.1 s), only 50%–60% visual features are activated, while at high speed (1.5 m/0.1 s), 60%–75% visual features are used.

VI. CONCLUSION AND FUTURE RESEARCH

We present a generic multimodal sensor fusion framework for deep state estimation, in support of odometry estimation and global relocalization tasks. Motivated by the need for robust interpretable sensor fusion in real-world applications, we propose two variants of selective fusion modules, i.e., a deterministic soft fusion and a Gumbel-softmax-based hard fusion, which can be integrated in different neural network frameworks. It can learn to perform sensor fusion on feature space from pairs of different modalities, e.g., vision-depth, vision-LIDAR, and vision-inertial data, conditioned on the input data itself. Extensive experiments illustrate that our proposed models outperform learning-based single modality and multimodal model with direct fusion baselines, and also show competitive performance over other classical approaches, though the performance is still inferior to the domain-specific state-of-the-art in some cases. It also demonstrates that learning models are generally more robust than conventional hand-designed algorithms, and our proposed SelectFusion can further improve the performance of basic learning models, and achieve more accurate results than other baselines in these degraded sets. By interpreting the learned fusion masks, we investigate the influence of different modalities with different types of motion and different levels of sensor degradation.

ACKNOWLEDGMENT

The authors would like to thank Yishu Miao from MolIntelligence, U.K., Wei Wu from Tencent, Shenzhen, China, and Wei Wang from the University of Oxford, Oxford, U.K., for helpful discussions. This work was done during Changhao Chen’s Ph.D. and post-doctoral study at the University of Oxford.

Changhao Chen (Member, IEEE) received the B.Eng. degree from Tongji University, Shanghai, China, in 2014, the M.Eng. degree from the National University of Defense Technology, Changsha, China, in 2016, and the Ph.D. degree from the University of Oxford, Oxford, U.K., in 2020.

He is currently a Lecturer with the College of Intelligence Science and Technology, National University of Defense Technology. His research interests lie in robotics, computer vision, and cyberphysical systems.

Stefano Rosa received the M.S. degree in computer engineering from the Politecnico di Torino, Turin, Italy, in 2008, and the Ph.D. degree in robotics from the Istituto Italiano di Tecnologia (IIT), Genoa, Italy, in 2014.

He is currently a Research Fellow with IIT. He was a Post-Doctoral Researcher with the University of Oxford, Oxford, U.K., working on the EPSRC Program Grant “Mobile Robotics: Enabling a Pervasive Technology of the Future.” His research interests include localization and mapping for mobile robotics, computer vision applied to robot navigation, and human–robot interaction.

Chris Xiaoqian Lu received the M.Eng. degree from Nanyang Technological University, Singapore, in 2015, and the Ph.D. degree from the University of Oxford, Oxford, U.K., in 2019.

He is currently an Assistant Professor with the School of Informatics, The University of Edinburgh, Edinburgh, U.K. His research interest lies in cyber physical systems, which use networked smart devices to sense and interact with the physical world.

Bing Wang received the B.Eng. degree from Shenzhen University, Shenzhen, China, in 2016. He is currently pursuing the Ph.D. degree with the Department of Computer Science, University of Oxford, Oxford, U.K.

His research interests lie in camera localization; feature detection, description, and matching; and cross-domain representation learning.

Niki Trigoni is currently a Professor with the Department of Computer Science, University of Oxford, Oxford, U.K. She is also the Director of the EPSRC Centre for Doctoral Training on Autonomous Intelligent Machines and Systems, University of Oxford; and leads the Cyber Physical Systems Group. Her research interests lie in intelligent and autonomous sensor systems with applications in positioning, healthcare, environmental monitoring, and smart cities.

Andrew Markham received the B.Sc. and Ph.D. degrees from the University of Cape Town, Cape Town, South Africa, in 2004 and 2008, respectively.

He is currently an Associate Professor with the Department of Computer Science, University of Oxford, Oxford, U.K. He is also the Director of the M.Sc. program in software engineering. He works on resource-constrained systems, positioning systems, in particular magneto-inductive positioning and machine intelligence.
