Abstract. The hidden Stueckelberg $Z'$ model is augmented by a pair of Dirac fermions. If the $Z'$ has a coupling strength comparable to weak scale coupling, one can show that this hidden fermion-antifermion pair could be a milli-charged dark matter candidate with a viable relic density. Monoenergetic photon flux coming from the Galactic center due to pair annihilation of these milli-charged particles is calculated and is shown to be within reach of the next generation gamma-ray experiments. Characteristic collider signature of this theoretical endeavor is that the Stueckelberg $Z'$ boson has a large invisible width decaying into the hidden fermion-antifermion pair if kinematically allowed. Singly production of this $Z'$ boson at the LHC and ILC are studied.

1 Stueckelberg $Z'$ Extension of Standard Model (StSM)

The standard electroweak model (SM) based on the gauge group $SU_L(1) \times U_Y(1)$ was extended in \cite{1} by including an additional hidden $U_X(1)$ endowed with two Stueckelberg mass terms for the two abelian groups (StSM),

\[ \mathcal{L}_{\text{StSM}} = \mathcal{L}_{\text{SM}} + \mathcal{L}_{\text{St}} \]

\[ \mathcal{L}_{\text{St}} = -\frac{1}{4} C_{\mu \nu} C^{\mu \nu} + \frac{1}{2} (\partial_{\mu} \sigma + M_1 C_{\mu} + M_2 B_{\mu})^2 - g X C_{\mu} \mathcal{J}^{\mu}_X, \]

where $\sigma$ is the Stueckelberg axion field, $B_{\mu}$ and $C_{\mu}$ are the gauge fields for the hypercharge $U_Y(1)$ and hidden $U_X(1)$ respectively, and $\mathcal{J}^{\mu}_X$ is the current associated with the hidden gauge field. This model is unitary and renormalizable. Upon electroweak symmetry breaking by the Higgs mechanism $\langle \Phi \rangle = v/\sqrt{2}$, the $3 \times 3$ mass matrix for the neutral gauge bosons takes the following form

\[ M_{\text{St}}^2 = \begin{pmatrix} M_1^2 & M_1 M_2 & 0 \\ M_1 M_2 & M_2^2 + \frac{1}{4} g_Y^2 v^2 - \frac{1}{4} g_{2g_Y} v^2 & 0 \\ 0 & -\frac{1}{4} g_{2g_Y} v^2 & \frac{1}{4} g_Y^2 v^2 \end{pmatrix} \]

where $g_2$ and $g_Y$ are the two gauge couplings for the $SU_L(2)$ and the hypercharge $U_Y(1)$ respectively. Note that the vanishing of the determinant of $M_{\text{St}}^2$ guarantees a zero mode that can be identified as the photon. For the other two massive states, one is the standard model $Z$ and the other a new Stueckelberg $Z'$. Using the precision electroweak data from LEP to constrain the $Z$ mass shift, it was shown in \cite{2} that

\[ |\delta | = |tan \phi - M_2/M_1| \leq 0.061 \sqrt{1 - (m_{Z'}/M_1)^2} \]

assuming $m_{Z'/M_1} \ll 1$. Furthermore, if one assumes $\mathcal{J}_X = 0$, the $Z'$ couplings to the SM fermions will be suppressed by the mixing angles which parameterize the orthogonal matrix that diagonalizes the mass matrix \cite{2}. This implies a very narrow $Z'$ width, typically of order MeV. Consequently, the Drell-Yan data from the Tevatron can only constrain the Stueckelberg $Z'$ mass as

\[ m_{Z'} > 250 \text{ GeV for } \delta \approx 0.035 , \]

\[ m_{Z'} > 375 \text{ GeV for } \delta \approx 0.06 , \]

which are much lower than those arising from other more conventional $Z'$ models \cite{2}.

2 Hidden Fermions

In \cite{3}, a hidden Dirac fermion $\chi$ and its antiparticle $\bar{\chi}$ were added in the above StSM such that the hidden current $\mathcal{J}^{\mu}_X = \bar{\chi} \gamma^{\mu} Q_X \chi$ is no longer vanish. After rotation to the physical mass eigenstates of the neutral gauge bosons, this hidden fermion couples not only to the Stueckelberg hidden $Z'$ but also the photon $A$ and the SM $Z$ boson as well. Thus the neutral current becomes

\[ -\mathcal{L}_{\text{int}}^{NC} = g_X C_{\mu} \mathcal{J}_X^{\mu} = \cdots + \bar{\chi} \gamma^{\mu} \left[ \epsilon_X^A A_{\mu} + \epsilon_X^Z Z_{\mu} + \epsilon_{Z'} Z_{\mu}' \right] \chi . \]

Drell-Yan process

Constraint from preliminary CDF data for the Fig. 2.

LEPII constraint from

Alternatives Contributed Talk

If one assumes $Z$ mixing angles. This implies the $\epsilon$ with the coupling strengths $m$ energy with $c$ where $Z$ input values of parameters, the $Z$ further loosened in this scenario. We can illustrate this by two plots: Fig.[1] for $e^-e^+ \rightarrow Z' \gamma \rightarrow \gamma + \text{missing energy}$ from DELPHI data [4] of LEP and Fig.[2] for Drell-Yan process $p\bar{p} \rightarrow Z' \rightarrow e^-e^+$ from the CDF preliminary data [5] of Tevatron. Branching ratio of the $Z'$ is also plotted in Fig.[3] for $m_\chi = 60$ GeV. On the decay channel $Z'\rightarrow \chi\bar{\chi}$ is open, it dominates over all other modes.

On the other hand, the mixing effects induce an electric charge $e_{\chi}^c/\epsilon$ for the hidden fermion $\chi$. This charge is not quantized and can be in the interesting milli-charge range depending on the mixing angles. Since $\chi$ is stable in the present model, this provides an alternative milli-charged dark matter candidate for astrophysics. Milli-charged fermion had been considered as dark matter candidate some time ago [6] in a different context [7]. See also [8] and [9] for integral and composite charged dark matter respectively. For various experimental limits on milli-charged particles, see [10].

3 Astrophysical Implication

3.1 Relic density calculation

Recent three year integrated WMAP data [11] implies the following constraint for any relic of cold dark matter (CDM) in our universe

$$\Omega_{\text{CDM}} h^2 = 0.1045^{+0.0072}_{-0.0066}.$$  \hspace{1cm} (4)

The relic density is related to the annihilation cross section $\langle \sigma v \rangle$ by the following approximation [12]

$$\Omega_{\text{CDM}} h^2 \simeq \frac{0.1 \text{ pb}}{\langle \sigma v \rangle}.$$  \hspace{1cm} (5)

From Eq.(4), one can translate the WMAP constraint onto the annihilation cross section

$$\langle \sigma v \rangle \simeq 0.95 \pm 0.08 \text{ pb}.$$  \hspace{1cm} (6)

In our relic density calculation [13], we include the following processes $\chi\bar{\chi} \rightarrow f_{\text{SM}} \bar{f}_{\text{SM}}$, $\gamma Z'$ and $ZZ'$. Thermal average in $\sigma v$ was ignored and $v^2 \simeq 0.1$ was used for the relative velocity of the annihilating dark matter. In Fig.4, the contour plot of $\sigma v$ as restricted by [6] is exhibited as function of the two unknown masses $m_{\chi}$ and $m_{Z'}$ with $g_X Q_X^\chi = g_2$ and $\delta = 0.03$. The upper curves and lower straight lines correspond to the case where the channel $Z'\rightarrow \chi\bar{\chi}$ is open and close respectively. One can see that the allowed region for the masses for both $Z'$ and $\chi$ are accessible by the LHC. More elaborated calculation of the relic density including proper thermal averaging of $\langle \sigma v \rangle$ over the resonant $Z'$ carried out in [13] do not alter our result significantly.
3.2 Indirect search

After freeze out, pair annihilation of $\chi$ and $\bar{\chi}$ becomes greatly suppressed. However, at later times after the structure formation, $\chi \bar{\chi}$ annihilation may regain its importance in the dense region of our universe like the center of the galaxy. Thus monochromatic photon line from the processes $\chi \bar{\chi} \rightarrow \gamma \gamma, \gamma Z, \gamma Z'$ could be the “smoking-gun” signal of dark matter annihilation at our Galaxy center, which may be detected by various ACT array or space satellite experiments. The gamma-ray flux is given by [14]

$$\Phi_\gamma(\Delta \Omega, E) \approx 5.6 \times 10^{-12} \frac{dN_\gamma}{dE} \left( \frac{\sigma v}{\text{pb}} \right) \left( \frac{1 \text{ TeV}}{m_\chi} \right)^2 \times J(\Delta \Omega) \Delta \Omega \text{ cm}^{-2} \text{ s}^{-1}$$

with $dN_\gamma/dE$ being the photon energy spectrum (a Dirac delta function $\delta(E - E_\gamma)$ in our case) and the quantity $J(\psi)$ defined by

$$J(\psi) = \frac{1}{8.5 \text{ kpc}} \left( \frac{1}{0.3 \text{ GeV/cm}^2} \right)^2 \times \int_{\text{line of sight}} ds \rho^2(r(s, \psi)) .$$

Note that $J(\psi)$ depends on the halo profile $\rho$ of the dark matter and its values may vary over several order of magnitudes [14]. TeV gamma-rays from Sgr A* (a hypothetical super-massive black hole) near the Galactic center had been observed recently by CANGAROO [15], HESS [16] and VERITAS [17]. While these high energy gamma-rays are generally believed to have a violent astrophysical origin, they may play the role of continuum background for dark matter detection. Detectability of photon line above continuum background at GLAST [18] and HESS [19] was studied in [20], where the following criteria was derived by extrapolating the TeV data to lower energy

$$\text{Photon flux} \geq 1.9 \times \left( \frac{\text{TeV}/m_\chi}{10^{-14} - 10^{-13}} \right) \text{ cm}^{-2} \text{ s}^{-1} .$$

In Fig. 5, the photon fluxes from $\chi \bar{\chi}$ annihilation into $\gamma \gamma, \gamma Z, \gamma Z'$ near the Galaxy center as a function of $m_\chi$. The cross section for $Z' \rightarrow \chi \chi$ has been set to be unity.

4 Collider Implication

4.1 Large Hadron Collider (LHC)

Masses for the Stueckelberg $Z'$ and the hidden fermion $\chi$ in the range of a few hundred GeV are seen to be compatible with the WMAP data. Discoveries of these new particles at the LHC or at a future $e^- e^+$ collider are thus feasible. In Fig. 6, we plot the cross section for singly production of $Z'$ along with a monojet due to the parton process $q \bar{q} \rightarrow Z' j$. Since $Z' \rightarrow \chi \chi$, the signal would be monojet plus missing energy. The transverse momentum $p_T > 20 \text{ GeV}$ and rapidity $|y_j| < 2.5$.
cuts were imposed on the jet. Moreover, the input values of $g_X Q_X^2$ and $\delta$ are chosen to be those suggested by the above relic density calculation.

4.2 International Linear Collider (ILC)

At the ILC, one can look for singly $Z'$ production together with a monochromatic photon with energy fixed by the $m_{Z'}$ mass and center of mass energy. The total cross section as a function of $m_{Z'}$ is plotted in Fig. 7 for three different ILC center of mass energies of 0.5, 1 and 1.5 TeV. We have imposed the cuts of $E_\gamma > 10$ GeV on the photon energy and $-1 < \cos \theta_\gamma < +1$ for the angle of the photon momentum with respect to the beam axis in these curves. As in the previous subsection, we chose $g_X Q_X^2 = g_2$ and $\delta = 0.03$.

5 Conclusion

Adding a pair of Dirac fermion-antifermion in the hidden Stueckelberg $U_X(1)$ sector provides interesting phenomenology for both collider physics and astrophysics. We have demonstrated that if the gauge coupling of the hidden $U_X(1)$ sector has a comparable size like the electroweak gauge group, the hidden fermion carries milli-charge and can be served as an alternative dark matter with a viable relic density suggested by the WMAP data. Pair annihilation of the hidden fermions at the Galactic center can give rise to a “smoking-gun” signal of monochromatic line that may be above the continuum background and therefore can be probed by the next generation of gamma-rays experiments. Moreover, both the hidden fermion and the Stueckelberg $Z'$ can have mass range in a few hundred GeV without any conflict with existing data. If the decay of $Z'$ into hidden fermion-antifermion pair is kinematically allowed, this provides a new invisible decay mode for $Z'$ other than the neutrinos. The $Z'$ width is no longer narrow but its dominant decay mode is the invisible mode $\chi \bar{\chi}$. Thus it provides new challenge to search for such new neutral gauge boson at the LHC or ILC. To search for these new particles, we propose to use the signals of monojet plus missing energy at the LHC and single photon plus missing energy at the ILC.
