Effective Small Interfering RNA Therapy to Treat CLCN7-dependent Autosomal Dominant Osteopetrosis Type 2

Mattia Capulli1, Antonio Maurizi1, Luca Ventura2, Nadia Rucci1 and Anna Teti1

In about 70% of patients affected by autosomal dominant osteopetrosis type 2 (ADO2), osteoclast activity is reduced by heterozygous mutations of the CLCN7 gene, encoding the ClC-7 chloride/hydrogen antiporter. CLCN7R767W, CLCN7R726W, and CLCN7G213R-specific siRNAs silenced transfected mutant mRNA/EGFP in HEK293 cells, in RAW264.7 cells and in human osteoclasts, with no change of CLCN7WT mRNA and no effect of scrambled siRNA on the mutant transcripts. Osteoclasts from Clcn7G213R ADO2 mice showed reduced bone resorption, a condition rescued by Clcn7G213R-specific siRNA. Treatment of ADO2 mice with Clcn7G213R-specific siRNA induced increase of bone resorption variables and decrease of trabecular bone mass, leading to an overall improvement of the osteopetrotic bone phenotype. Treatment did not induce overt adverse effects and was effective also with siRNAs specific for other mutants. These results demonstrate that a siRNA-based experimental treatment of ADO2 is feasible, and underscore a translational impact for future strategy to cure this therapeutically neglected form of osteopetrosis.

Molecular Therapy—Nucleic Acids (2015) 4, e248; doi:10.1038/mtna.2015.21; published online 1 September 2015

Subject Category: siRNAs, shRNAs, and miRNAs Therapeutic proof-of-concept

Introduction

Autosomal dominant diseases are often characterized by severe morbidity and lack of effective treatments.1–3 Consistent with the dominant negative nature of these genetic conditions, they are fairly good candidates for mutant gene silencing by RNA interference.4,5

RNA interference is a mechanism by which gene expression is regulated at the post-transcriptional level.6 It relies on the ability of cells to transcribe and process small RNAs that complement specific mRNA sequences, inducing their degradation.6,7

Experimental RNA interfering occurs by two principal molecules, the small hairpin (sh)RNAs and the small interfering (si)RNAs.8 To silence an mRNA by shRNA, transfection vectors must be used to transduce cells, which will then express and process the shRNA to make it active in gene silencing.9 From a therapeutic point of view, shRNA delivery requires approaches similar to gene therapy, which would limit its use especially to local diseases.8 siRNA are instead double-strand 15 to 25 nucleotide sequences that freely influx the cells.10 Transfection agents may improve the efficiency of siRNA delivery, but especially for primary cells, they are not always strictly necessary.11 siRNAs are generally highly specific and efficient in silencing gene expression12 and, therapeutically, they are gaining great interest for the theoretical possibility to be used in clinic to treat systemic conditions, such as those caused by neoplastic somatic mutations13 or by germline dominant negative genetic alterations.14 siRNA sequences can be designed to complement a given mRNA in a highly specific and efficient manner,15 with a certain degree of serendipity still necessary to obtain effective gene silencing.15,16

Especially in cancer, siRNAs have been found to be suitable for targeted therapies in animal models, and clinical trials are currently being developed to eliminate deregulated pathways that transform cells and make them aggressive.16–18 Recent work pointed to the use of siRNAs also in osteopetrosis, especially targeting pathways implicated in osteoclastogenesis and bone resorption.19 Various modifications are being tested to improve stability, pharmacokinetics, delivery reproducibility, and tissue distribution.16,19 In addition, diverse vehicles have been found to improve stability and availability, concuring to optimize the use in vivo and minimize siRNA immune and inflammatory responses.13,20,21 The number of diseases hypothesized to be cured by siRNA therapy, including autosomal dominant genetic disorders, is steadily increasing. It has been observed that siRNAs can distinguish mRNA species also by a single divergent nucleotide,22 and there are means to increase specificity,23 with the result that only the mutant mRNA undergoes degradation, with no effect on the normal mRNA.24

Autosomal dominant osteopetrosis type 2 (ADO2), or Albers-Schönberg disease,25 is a genetic bone condition due, in roughly 70% of patients, to heterozygous missense mutations of the CLCN7 gene. This gene encodes the CIC-7 protein, formerly considered a chloride channel (type 7),26 but now reclassified as a chloride/hydrogen antiporter.27 CIC-7 is expressed in various organs, including bone, liver, kidney, heart, spleen, and brain,26 but its mutations greatly affect especially bone and brain. CLCN7 loss-of-function mutations lead to autosomal recessive osteopetrosis, characterized by severe skeletal and, often, cognitive phenotype.28 In bone, stunted growth, increased bone mass, and constrain of the bone marrow cavities are observed along with extreme...
bone fragility, hematological failure, recurrent infections, and osteomyelitis.

In the bone tissue, the mutation affects the osteoclasts, multinucleated cells that disrupt the bone matrix through the acidification of the extracellular space confined between the osteoclast plasma membrane and the bone surface, called resorption lacuna. Here protons are released through a vacuolar H^+ -ATPase and this release is charge balanced by the CLC-7 protein that discharges chloride ions into the resorption lacuna. Neural impairments, typically due in autosomal recessive osteopetrosis to nerve compression syndromes, in this form can be aggravated by primary hippocampal, cortical and retinal degeneration caused by lysosomal storage disease. The CLCN7 gene is apolysosin, and single allele loss of function mutant carriers display no symptoms whatsoever.21,32

At variance with autosomal recessive osteopetrosis, CLCN7-dependent ADO2 is not life threatening but can be seriously debilitating. It presents with dense bones, especially at skull base, pelvis, and vertebrae. 66% of the patients show disease symptoms, which range from mild to severe, very rarely lethal, with the remaining patients representing unaffected carriers. Along with high bone mass, patients display bone fragility that, in the most severe cases, can cause tens of nontraumatic fractures, very difficult to be treated surgically. Osteomyelitis, reduced vision and hearing due to nerve compression, infections and some hematological failures are also observed in severe forms, while cognitive functions are generally preserved.32,33

CLCN7-dependent ADO2 has no cure. Palliative interventions to control pain, reduce fractures, decompress nerves, and improve hematological symptoms are used, with albeit poor effectiveness. Therefore, there is an urgent need to identify efficient methods to treat this therapeutically neglected disease. In this work, we hypothesized that CLCN7 mutant-specific siRNAs could be effective in silencing dominant negative CLCN7 transcripts in vitro and in vivo, representing an efficacious means to ameliorate the bone phenotype in ADO2. We tested our siRNA in an animal model of ADO2 (ref. 34) and found a treatment regimen that increased bone resorption and reduced bone mass, rescuing the bone phenotype to normal levels.

Results

Set-up of HEK293 cell models

In this study, we investigated three Clcn7 mutants, Clcn7G215R, Clcn7G213R, and Clcn7G213E. By site-directed mutagenesis, we obtained pEGFP-C1 vectors carrying the constructs with the desired mutation tagged with the EGFP (Table 1 and Figure 1a), that were used to transfect human HEK293 cells (Figure 1b–e), human peripheral blood mononuclear cells (see Figure 4a–c), human MDA-MB-231 cells (see Figure 4e), and mouse RAW264.7 cells (see Supplementary Figure S1).

siRNA design and in vitro tests

ADO2 CLCN7 mutations are shown in Supplementary Table S1. A series of CLCN7mutant-specific siRNAs were designed for the three mutations (Table 2 and Supplementary Table S1) and tested in transfected HEK293 cells for their ability to reduce CLCN7mutant expression in an efficient and highly specific manner. Scrambled siRNAs were used as negative controls. We observed that most siRNAs diverging from CLCN7mutant only for the mutant nucleotide, even if efficient, were not enough specific as they silenced to a similar extent also the CLCN7mutant mRNA (Table 2). According to Onishi et al.,24 we improved the specificity between CLCN7mutant-EGFP and CLCN7mutant-EGFP mRNA silencing by introducing additional mismatch nucleotides in various positions of the siRNAs (Table 2). Using our screening strategy, we selected one siRNA per each CLCN7 mutation that was effective in silencing the CLCN7mutant-EGFP in HEK293 cells without affecting the CLCN7mutant-EGFP (Table 2; Figure 1c–e). These siRNAs knocked down the CLCN7mutant-EGFP transcript also in transfected RAW264.1 cells, which represent a murine model of osteoclast precursors (Supplementary Figure S1).

Clcn7G213R gene silencing and bone resorption tests in mouse Clcn7G213R WT ADO2 osteoclasts

To perform the in vivo tests, we used the Clcn7G213R WT knock-in mice recently generated in our laboratory.24 These mice harbor the murine homolog (G213R) of the human CIC-7 G215R amino acid substitution and show a bone phenotype similar to the human disease, thus representing a genuine model of human ADO2. To induce Clcn7G213R gene silencing, we used the specific CLCN7G213R siRNA effective on the human mutant gene, which displayed the mutant nucleotide and one additional mismatch nucleotide compared to the murine wild-type sequence (Table 3). This siRNA was first tested ex vivo for its efficiency in decreasing osteoclast Clcn7G213R mRNA and rescuing bone resorption. To this end, bone marrow mononuclear cells were isolated from Clcn7G213R WT and Clcn7G213R WT ADO2 mice and differentiated into mature osteoclasts on plastic or bone slices. In this experimental condition, using primer pairs that discriminated the mutant from the normal mRNA form (Supplementary Table S2, Figure 1f–i), we observed that treatment of ADO2 osteoclasts with Clcn7G213R-siRNA reduced the transcriptional expression of Clcn7G213R without affecting the Clcn7WT transcript (Figure 1h) nor the expression of other genes of the Clcn family, such as Clcn5 and Clcn5 (Supplementary Figure S2). Clcn7G213R WT ADO2 osteoclasts displayed a resorption pit formation ability of 30% of Clcn7G213R WT osteoclasts (Figure 1i), mimicking the rate of reduced bone resorption observed in bona fide human ADO2 osteoclasts.33,35 Treatment with Clcn7G213R-siRNA improved bone resorption (Figure 1i), thus indicating an efficient rescue of activity of the Clcn7G213R WT ADO2 osteoclasts. Furthermore, although Clcn7G213R WT ADO2 cells formed more osteoclasts

| Mutation  | CLCN7G213R | CLCN7G213R | CLCN7G213R |
|-----------|------------|------------|------------|

Figure 1  *In vitro* and *in vivo* tests of CLCN7mutant-specific siRNAs. (a) Cartoon depicting the pEGFP-C1 vector used in the study. (b) HEK293 cells stably transfected with the pEGFP-C1 vector carrying the indicated mutations. Expression of the CLCN7 gene was quantified by real-time RT-PCR on RNA extracted from mutant transfectants, against cells transfected with the empty vector, which did not express CLCN7 mRNA (first bar from left). (c–e) HEK293 cells transfected with the indicated vectors, were treated with the CLCN7mutant-specific siRNA listed in Table 2 as the most effective per each mutation. Concentration-dependent regulation of CLCN7 assessed by real-time RT-PCR, normalized with GAPDH, (f) RT-PCR using primer pairs specific for the Clcn7G213R mRNA showing transcript amplification only in heterozygous (Clcn7G213RWT) and homozygous (Clcn7G213R/G213R) osteoclasts, while in wild-type osteoclasts (Clcn7WT/WT) no transcript was amplified. (g) Direct DNA sequencing of the amplified transcript shown in f for the Clcn7G213RWT osteoclasts, demonstrating only the mutant sequence. (h) Osteoclasts generated from the bone marrow mononuclear cells of Clcn7WT/WT and Clcn7G213R/WT mice were treated with the indicated concentration of scrambled (SCR) or Clcn7G213R-specific siRNA. Real-time RT-PCR was performed using the primer pairs specific for the mutant transcript validated in (f) and (g). (i) Osteoclasts were generated from the bone marrow mononuclear cells of Clcn7WT/WT and Clcn7G213R/WT mice onto bone slices and treated with the indicated concentration of SCR and Clcn7G213R-specific siRNA. At the end of experiment, cells were removed by sonication and bone resorption evaluated by the pit assay. (j) Three-month-old Clcn7WT/WT mice were injected once i.p. with 4 mg/kg of Clcn7G213R-sticky siRNA jetPEI conjugate and sacrificed at the indicated time point. Sera were collected and evaluated for total RNA concentration by Nanodrop. (k) Ten-day-old Clcn7G213R/WT mice were injected once i.p. with the indicated doses of SCR- or of Clcn7G213R-sticky siRNA jetPEI conjugate. After 48 hours, mice were sacrificed, RNA was extracted from tibias, and evaluated by real-time RT-PCR using the primer pairs specific for the Clcn7G213R mRNA validated in (f) and (g). In b–e, h–k data are the mean ± SD of three independent experiments or three animals/group. b–e,h,k: Student’s t-test; j: one-way analysis of variance (ANOVA). For c–e, statistics was also performed by one way ANOVA (shown in Supplementary Table S3).
than Clcn7<sup>WT/WT</sup> cells, suggesting no effect of treatment on osteoclast formation.

**Optimization of Clcn7<sup>G213R</sup>-siRNA in vivo delivery**

For *in vivo* experiments, our Clcn7<sup>G213R</sup>-siRNA was conjugated with the PolyPlus Transfection jetPEI reagent, a linear polyethyleneimine derivative providing effective and reproducible in *vivo* siRNA delivery, preventing inflammatory responses. To allow our Clcn7<sup>G213R</sup>-siRNA to efficiently conjugate with the jetPEI reagent, as suggested by the jetPEI reagent manufacturer, its sequence was modified by 3’dAdT overhangs that favor siRNA oligomerization and binding to jetPEI through the ADO2 bone phenotype, we treated mice with 4 mg/kg body weight Clcn7<sup>G213R</sup>-sticky siRNA/jetPEI with a frequency of three times a week.

**In vivo tests**

To assess whether Clcn7<sup>G213R</sup>-sticky siRNA/jetPEI could affect the ADO2 bone phenotype, we treated Clcn7<sup>G213R/WT</sup> mice with our conjugate, three times a week for 2 and 4 weeks. During the treatment, mice appeared healthy and active, with no signs of distress. At autopsy, we observed no gross alteration of visceral organs, confirmed also histopathologically (Figure 2a), and an improvement of serum biomarkers of kidney and liver diseases, along with a reduction of serum creatine kinase (Figure 2b). The Clcn7 transcript has a wide cellular distribution in human and mouse (Supplementary Figure S4), and in bone it is highly expressed especially in osteoclasts (Supplementary Figures S4b,c and S5). Real-time reverse transcriptase-polymerase chain reaction (RT-PCR) confirmed that Clcn7<sup>G213R</sup> mRNA expression was reduced in all organs tested but the brain (Figure 2c), suggesting no crossing of the blood–brain barrier. Since our mice did not show obvious central nervous system alterations.

and patients are generally reported not to suffer from cognitive failures,\(^32,33\) this circumstance should have no important consequences. Furthermore, the treatment appeared to be specific for the CLCN7 mRNA because we did not observe any off-target effect in femurs on CLCN3 and CLCN5 transcripts (Supplementary Figure S6).

Bone phenotype
To assess the bone phenotype of Clcn7<sup>G213R</sup>-sticky siRNA/jetPEI-treated ADO2 mice, we first evaluated the serum level of the bone resorption marker collagen type I cross-linked C-telopeptide (CTX) over the osteoclast marker Tartrate-Resistant Acid Phosphatase (TRACP) 5b isoform, and observed a significant increase compared to scrambled sticky siRNA/jetPEI conjugate-treated Clcn7<sup>G213R/WT</sup> mice, peaking after 2 weeks of treatment (Figure 2d), which suggested activated bone resorption. After 4 weeks, serum CTX concentration returned to lower levels, probably due to the reduced number of osteoclasts indicated by the decreased levels of TRACP (Figure 2d). These results suggest normalization of the osteoclast number, that in the Clcn7<sup>G213R/WT</sup> mice was higher than in the Clcn7<sup>WT/WT</sup> (see Figure 3g–i), and re-establishment of normal bone resorption.

After 2 weeks of treatment, µCT analysis of proximal tibias of Clcn7<sup>G213R/WT</sup> mice treated with Clcn7<sup>G213R/-</sup>sticky siRNA/jetPEI showed an improvement of the trabecular bone (Figure 2e) with significant decrease of trabecular bone volume over total tissue volume (Figure 2f), associated with decrease of trabecular number and thickness, and increase of trabecular separation (Figure 2g–i). These variables were further improved after 4 weeks of treatment, when we observed full rescue of the bone phenotype, with trabecular bone structural variables returning to the levels of wild-type mice (Figure 3a–e). Treated mice also showed a trend of reduction of ParaThyroid Hormone (PTH) (Figure 3f), decrease of osteoclast number over bone perimeter and osteoclast surface over bone surface (Figure 3g–i), and reduction of mRNA expression of osteoclast-specific genes (Figure 3j), which are in agreement with the reduced serum levels of TRACP (Figure 2d). Importantly, bone resorption was increased, as demonstrated by the larger erosion surface (Figure 3k) and the reduced trabecular cartilage remnants in the secondary spongiosa (Figure 3l) observed by histomorphometry. Clcn7<sup>G213R/WT</sup> mice showed no alteration of cortical bone (Figure 4a), growth plate (Figure 4b), femur length (Supplementary Figure S7), osteoblast (Figure 4c), osteoid (Figure 4e), and dynamic (Figure 4f–i) variables compared to Clcn7<sup>WT/WT</sup> mice, and these features were not affected by the treatment, suggesting no direct effect of Clcn7<sup>G213R/-</sup>sticky siRNA/jetPEI on bone formation, nor impairment of osteoclast-to-osteoblast crosstalk. Finally, the evaluation of indentation properties demonstrated a tendency of reduction of total indentation distance, significant reduction of first cycle indentation distance (Figure 4j,k) and significant increase of touchdown distance (Figure 4l), suggesting improvement of the biomechanical quality of the bones collected from the Clcn7<sup>G213R/-</sup>sticky siRNA/jetPEI-treated Clcn7<sup>G213R/WT</sup> mice. Taken together, these results suggest a successful in vivo experimental therapy for Clcn7<sup>G213R/WT</sup> ADO2 mice with Clcn7<sup>G213R/-</sup>-specific siRNA.

Treatment with human-specific siRNAs
In vitro treatment of human blood-derived osteoclasts, transfected with vectors carrying the CLCN7<sup>R767W-EGFP</sup>, the CLCN7<sup>R767W-EGFP</sup>, and the CLCN7<sup>R286W-EGFP</sup> mutants, with CLCN7<sup>mutant</sup>-specific siRNAs efficiently reduced all CLCN7<sup>mutant</sup> mRNAs (Figure 5a–c), suggesting that the therapy could be suitable also for human cells. By chance, we had access to the peripheral blood mononuclear cells of a Clcn7<sup>G213R/WT</sup> ADO2 patient, who presented with diffuse cranial and vertebral sclerosis, optic nerve compression, muscle hypotonia, reduced red cell count, low hemoglobin and hematocrit, and increased creatine kinase. In one single experiment, we could assess the efficacy of the CLCN7<sup>G213R/-</sup>-specific siRNA on bone resorption. We observed an increase of the pit area over bone section area in the osteoclasts treated with the CLCN7<sup>G213R/-</sup>-specific siRNA versus osteoclasts treated with the scrambled siRNA (Figure 5g). Although there are important limitations in testing the treatment in a single osteoclast culture from a single patient, this result could strengthen the hypothesis that the therapy could improve bone resorption also in human ADO2 osteoclasts.

Finally, in order to assess whether the siRNA targeting the human mutant gene could be used in vivo, we tested an alternative human/mouse model. We generated subcutaneous human tumors in atymic mice upon inoculation of human breast cancer MDA-MB-231 cells transfected with the CLCN7<sup>R767W/WT</sup> vector. These cells were sensitive to CLCN7<sup>R767W/-</sup>-specific siRNA treatment in vitro, showing a specific concentration-dependent downregulation of CLCN7<sup>R767W-EGFP</sup> chimeric mRNA (Figure 5e). Mice where then treated with a single i.p. injection of CLCN7<sup>R767W/-</sup>-specific siRNA, tumors were excised after 96 hours and examined for CLCN7<sup>R767W-EGFP</sup> chimeric RNA expression by RT-PCR. In this circumstance, we observed lesser CLCN7<sup>R767W-EGFP</sup> mRNA in tumors subjected to CLCN7<sup>R767W/-</sup>-specific siRNA treatment, with no effect induced by scrambled siRNA (Figure 5f).

Discussion
Our study demonstrates the feasibility of an effective treatment of murine CLCN7-dependent ADO2. To the best of our knowledge, this is the first report that describes a specific experimental cure for this therapeutically neglected disease, opening up an avenue for future developments in humans.
Figure 3 Rescue of the bone phenotype. Ten-day-old Clcn7WT/WT and Clcn7G213R/WT were treated with 4 mg/kg of scrambled- (SRC) or Clcn7G213R-sticky siRNA jetPEI conjugate, three times a week for 4 weeks. At the end of the experiments, mice were sacrificed and their bone phenotype analyzed. (a) µCT analysis of proximal tibias. (b) Trabecular bone volume over total tissue volume (BV/TV). (c) Trabecular number (Tb.N). (d) Trabecular thickness (Tb.Th). (e) Trabecular separation (TB.Sp). (f) Serum concentration of Parathyroid Hormone (PTH). (g) Histochemical TRAcP staining to evaluate osteoclasts (purple cells). Bar = 100 µm. (h) Osteoclast surface over bone surface (Oc.S/BS). (i) Osteoclast number over bone perimeter (Oc.N/B.Pm). (j) Transcriptional expression, by real-time RT-PCR on RNA extracted from the whole femurs of osteoclast (Tracp and Cathepsin K (CatK)) and osteoblast (Alkaline phosphatase (ALP) and Runt-related transcription factor 2 (Runx2)) genes normalized with gapdh. (k) Eroded surface over bone surface (ES/BS). (l) Representative images of the secondary spongiosa (upper panels) and measurement of cartilage area/trabecular area (lower panel). Arrows: cartilage remnants. Bar = 50 µm. Results are (a,g,i (upper panels)) representative or (b–f,h–l (lower panel)) the mean ± SD of three to seven mice/group (Student’s t-test). In d, P > 0.2. For b–f,h–l statistics was also performed by one-way analysis of variance (shown in Supplementary Table S3).
The positive effects of siRNA treatment were already appreciable after 2 weeks, and after 4 weeks there was a rescue of the bone phenotype, which included normalization of osteoclast and bone resorption serum biomarkers, bone structural and osteoclast variables. Early detection of reduced serum TRAcP and increased CTX has a great translational relevance as these parameters could be used in patients to monitor the progression of the treatment. Notably, the reduced serum TRAcP level in treated mice indicates normalization of osteoclast number, confirmed also by histomorphometry, suggesting that the treatment also interferes with the pressure to osteoclastogenesis typical of ADO2. In fact, in our siRNA-treated mice, we observed a trend to decrease of PTH, known to be implicated in osteoclastogenesis true its ability to increase RANKL and reduce osteoprotegerin expression. The concomitant increase of serum CTX and of the CTX/TRAcP ratio suggest that in the treated mice there were less numerous but more active osteoclasts. This result, along with the increased erosion surface and the reduced trabecular cartilage remnants in secondary figures.
spongiosa, suggest that indeed the siRNA used in this study efficiently targeted the osteoclasts in vivo, directly improving their activity, while there was no evidence of siRNA effect on osteoblasts, in vivo.

Consistently, treatment with siRNA efficiently targeted the osteoclasts in vivo, spongiosa, suggesting that indeed the siRNA used in this study successfully treated only palliatively.32 Recent preclinical treatment, partially improving the bone phenotype, has been demonstrated for interferon-γ, a cytotoxic and immunomodulator agent.41 However, interferon-γ is known to frequently cause important adverse effects, including suppression of bone marrow function, flu-like symptoms, diarrhea, fatigue, reduced ability to fight infections, confusion, etc., which are not expected in our study, considering the specificity of our targeted therapy.

Our results clearly show that our Clcn7R767W-specific siRNA can prevent the increase of bone mass in growing ADO2 mice. It will be necessary to test the therapy in adult and aging mice to ascertain its efficacy also in reducing the bone mass later in life. Our preliminary results, obtained injecting 3-month-old mice with Clcn7R767W-specific siRNA at the same regimen used in this study, show that indeed this is the case. However, further work is necessary to consolidate this observation.

siRNA specificity allows the suppression of virtually all genes, provided that they are correctly designed. Somatic mutations in cancer18 and germline missense dominant negative mutations14 are considered excellent targets for siRNA silencing. However, mRNAs with single nucleotide mutations, as those generally observed in genetic dominant diseases, are difficult to eradicate, and “trial and error” strategies are
generally used to identify effective and highly specific siRNA candidates. This has been done in our study, taking advantage of previous reports showing that additional nucleotide mismatches could allow satisfactory discrimination between mutant and normal mRNAs. In fact, we have obtained a series of siRNAs specific and effective for three human CLCN7 ADO2 mutations, one of which could be tested also in the only available Clcn7-dependent ADO2 mouse model. Our study confirmed that the systemic delivery is efficient when our siRNA is modified by 3’ dAdT overhangs and conjugated with the PolyPlus Transfection jetPEI linear polyethylenimine derivative. Improved stability and distribution, as well as prevention of immune and inflammatory responses to the siRNA, are important features to be considered for in vivo treatments, and our strategy appeared fully successful in this respect. We observed no adverse events in our mice, or signs of suffurance or distress during the entire length of our treatment.

In our study, we did not observe off-target effects of Clcn7siRNA on Clcn3 and Clcn5 transcripts, suggesting high specificity of the proposed treatment. However, we could not address specificity against a large part of the genome, therefore further work is necessary to rule out any potential undesirable off-target influence. Nevertheless, since this is a concern for any type of RNA interference therapy, there are great attention and effort, especially by companies, to identify appropriate strategies, including chemical modifications and rational design filters, to overcome this potential problem.

Further means to reduce off-target effects could be to specifically deliver the siRNA to the osteoclasts, which represent that main cell type implicated in ADO2. Associations of siRNA to liposomes, nanoparticles, exosomes and other types of extracellular vesicles could be considered promising targeted delivery strategies if they could be conjugated with highly specific osteoclast-seeking factors. However, due to the wide distribution of the CLCN7 gene expression, we believe that targeting multiple cell types could only be beneficial to improve the phenotype if the siRNA knocks down exclusively the target gene.

siRNA therapy is believed to become the gold standard treatment for certain diseases. Clinical trials are currently ongoing for a number of pathologies, with a more rapid progress for those with a local extension, such as ocular impairments. No doubt, however, that there is a great interest to develop systemic treatments for which siRNAs rather than shRNAs are probably more suitable. In fact, shRNAs entail the diseased cells to be transduced to express the silencing molecule endogenously, a condition that typically requires gene-like therapy. Although gene therapy is developing fast in recent years, it is still confined to selected genetic diseases especially characterized by immunodeficiency. siRNA therapy would instead have the advantage to be injectable by standard methods and be theoretically suitable for systemic delivery. In our experimental setting, the duration of gene silencing is 48 hours, which implies frequent redosing to maintain stable knock down. To reduce this burden, siRNAs should be made stable with a pharmacokinetics appropriate for a prolonged use. Considering the current great effort to obtain these conditions, we are confident that future developments will allow an easy use of siRNA also for systemic human diseases.

Long-term systemic injectable therapies have the disadvantage to reduce compliance. Furthermore, long-term adverse effects are currently unpredictable because longitudinal clinical studies must be accumulated over the years to address this concern. However, it is possible to hypothesize that in CLCN7-dependent ADO2, the treatment could be compulsory especially during the growth phase, when bone modeling and remodeling are very active and osteoclast bone resorption is essential for the proper accrual, shaping, and homeostasis of the skeleton. In adulthood, bone remodeling serves especially for preserving a healthy bone mass. Therefore, we can predict that siRNA treatment could be lessened or given discontinuously, with a better compliance. To date, we are not able to make any speculation on this specific aspect. However, other long-term injectable treatments, such as insulin therapy for diabetes, are already in use for millions of patients, allowing us to predict that it will not be difficult to adjust the siRNA treatments also for the long-term use.

In conclusion, this work has demonstrated the feasibility of a siRNA-based therapy for Clcn7-dependent ADO2, opening an avenue for the cure of this disease. Further studies are now necessary to consolidate this knowledge and translate the results into benefits for patients.

Materials and methods

Materials. Dulbecco’s modified minimum essential medium (DMEM), fetal bovine serum, penicillin, streptomycin, and trypsin were from Gibco (Uxbridge, UK). Sterile plastic ware was from Falcon Becton-Dickinson (Cowley, Oxford, UK) or Costar (Cambridge, MA). Trizol reagent, primers, and reagents for RT-PCR were from Invitrogen (Carlsbad, CA). The Brilliant SYBR Green QPCR master mix was from Stratagene (La Jolla, CA). Human recombinant (hr) Receptor Activator of Nuclear Factor κ-light-chain-enhancer of activated B cells transcription factor Ligand (RANKL) (#310-01) and hrMacrophage-Colony Stimulating Factor (M-CSF) (#300–25) were from Peprotech (EC, London). The cationic polymer transfection reagent in vivo-jetPEI (cat# 201-50G) was from Polyplus-Transfection (Illkirch, France). Scrambled siRNA and siRNAs specific for all the CLCN7 mutants were purchased by GE Dharmacon (Lafayette, CO). The Mouse TRAcP 5b isoform kit and the RatLaps EIA kit for CTX detection and bovine bone slices (cat. N. DT-1BON1000-96) were from Immunodiagnostic Systems (Gaithersburg, MD). Mouse PTH 1–84 ELISA kit (cat.#60–2305) was from Immunotopics (San Clemente, CA). The Reflotron kits were from Roche Diagnostics (Manheim, Germany). All the other reagents were of the purest grade from Sigma Aldrich (St. Louis, MO).

Animals. Procedures involving animals and their care were conducted in conformity with national and international laws and policies (European Economic Community Council Directive 86/609, OJ L 358, 1, December 12, 1987; Italian Legislative Decree 4.03.2014, n.26, Gazzetta Ufficiale della Repubblica Italiana no. 61, March 4, 2014).

Cells lines. The Human Embryonic Kidney 293 (HEK293), the human breast cancer MDA-MB-231, and the mouse leukemic monocyte-macrophase RAW264.7 cell lines were obtained...
from the American Tissue Culture Collection (ATCC, Rockville, MD) and grown in DMEM supplemented with 10% fetal bovine serum, 100 IU/ml penicillin, 100 µg/ml streptomycin, and 2 mM/l L-glutamine, in a humidified 95% air/5% CO2 incubator at 37 °C.

**Osteoclast primary cultures.** Bone marrow flushed out from the bone cavity of the long bones of 7-day-old mice (C57BL6/J background) was diluted 1:1 in Hank's balanced salt solution, layered over Histopaque 1077 solution and centrifuged at 400 g for 30 minutes. Cells were washed twice with Hank's solution, resuspended in DMEM, and plated in culture dishes at a density of 10^6 cells/cm². After 3 hours, cultures were rinsed to remove nonadherent cells and maintained for 7 days in the same medium supplemented with 50 ng/ml rhM-CSF and rhRANKL (120 ng/ml).

Human osteoclasts were differentiated from the peripheral blood mononuclear cells. Diluted blood (1:1 in Hank's solution) was layered over Histopaque 1077 solution and centrifuged at 400 g for 30 minutes. Buffy-coat cells thus isolated were washed twice with Hank's solution, resuspended in DMEM containing 10% fetal bovine serum, and plated in culture dishes at a density of 10^6 cells/cm². After 3 hours, cultures were rinsed to remove nonadherent cells and incubated for 2 weeks in the same medium, in the presence of 50 ng/ml M-CSF and 30 ng/ml RANKL.

**In vitro bone resorption assay.** Osteoclasts were differentiated as described above but onto bone bone slices. Slices were cleaned free of cells and stained with 1% toluidine blue. The pit area was then computed and expressed as % of bone resorption.

**Stable transfection.** The pEGFP-C1 plasmid was used because it allowed the generation of a chimeric CLCN7-EGFP transgene that could be identified through the EGFP tag. The vector backbone also contained a neomycin resistance cassette, used for the selection of stably transfected cells. HEK293 and RAW264.7 cells were stably transfected using lipofectamine reagent. These cells were used for in vitro siRNA screening.

MDA-MB-231 cells stably transfected with the pEGFP:C1/EGFP plasmid carrying the CLCN7 WT mutant gene were injected with jetPEI conjugated sticky scrambled-siRNA. The jetPEI solution and the siRNAs were dissolved in 100–150 µl of ddH2O supplemented with 5% glucose, according to the manufacturer's instructions.

**Micro computed tomography (μCT) analysis.** Images from tibias fixed in 4% formaldehyde were acquired in a SkyScan 1174 with a resolution of 6 µm (X-ray voltage 50 kV). Image reconstruction was carried out employing a modified Feldkamp algorithm using the SkyScan Nrecon software. 3D and 2D morphometric parameters were calculated for the trabecular bone (350 consecutive slides, 6 µm thick) starting 300 µm from the growth plate. The cortical thickness was analyzed in 100 consecutive slides, 6 µm thick, starting 2.1 mm from the growth plate. Threshold values were applied for segmenting trabecular bone corresponding to bone mineral density values of 0.6/cm³ calcium hydroxyapatite. 3D parameters were based on the analysis of a Marching Cubes type model with a rendered surface. Calculation of all 2D areas and perimeters was based on the Pratt algorithm.

**Bone histomorphometry.** Tibias fixed in 4% paraformaldehyde were dehydrated in ethanol and processed for methacrylate embedding without decalcification. Histomorphometric measurements were carried out on 5-µm thick sections with an interactive image analysis system (IAS 2000; Delta Sistemi, New Therapy for Autosomal Dominant Osteopetrosis

Copiti et al.

www.moleculartherapy.org/mtna
Rome, Italy)\textsuperscript{51} and with the suggested nomenclature.\textsuperscript{52} The analysis was performed in the proximal tibia trabecular region, 50 µm inside the cortical bone 100–450 µm below the growth plate. For the cartilage remnants, the analysis was performed in the secondary spongyosa, 450–650 µm below the growth plate and 50 µm inside the cortical bone. Osteoclast number/ bone perimeter (number/mm) and osteoclast surface/bone surface (%) were evaluated after histochemically staining the sections for TRACP activity. Osteoblast surface/bone surface (%) was evaluated after staining the sections with toluidine blue, while dynamic assessment of the mineral apposition rate was calculated after double injection of calcein, 10 and 3 days before sacrifice. Bone formation rate was calculated according to the following formula: mineral apposition rate × mineralized surface/bone area as suggested by Dempster et al.\textsuperscript{52}

**Statistics.** Results are expressed as the mean ± SD of at least three independent experiments or mice/group. Statistical analyses were performed by the Student’s t-test or the one-way analysis of variance, according to the type of data sets. Statistical methods are indicated in the figure legends and in **Supplementary Table S3.** A P value of <0.05 was conventionally considered statistically significant.
