(Dated: 4 March 2015)

We propose a decision criterion for segmenting the cosmic web into different structure types (voids, sheets, filaments and clusters) on the basis of their respective probabilities and the strength of data constraints. Our approach is inspired by an analysis of games of chance where the gambler only plays if a positive expected net gain can be achieved based on some degree of privileged information. The result is a general solution for classification problems in the face of uncertainty, including the option of not committing to a class for a candidate object. As an illustration, we produce high-resolution maps of web-type constituents in the nearby Universe as probed by the Sloan Digital Sky Survey main galaxy sample. Other possible applications include the selection and labeling of objects in catalogs derived from astronomical survey data.

I. INTRODUCTION

Building accurate maps of the cosmic web from galaxy surveys is one of the most challenging tasks in modern cosmology. Rapid progress in this field took place in the last few years with the introduction of inference techniques based on Bayesian probability theory (Kitaura et al., 2009; Jasche et al., 2010; Jasche, Leclercq & Wandelt, 2015). This allows the connection between the properties of the cosmic web, thoroughly analyzed in simulations (e.g. Hahn et al., 2007; Aragón-Calvo, van de Weygaert & Jones, 2010; Cautun et al., 2014), and observations (see Leclercq, Pisani & Wandelt, 2014, for a review on the interface between theory and data in cosmology).

In Leclercq, Jasche & Wandelt (2015), we conducted a fully probabilistic analysis of structure types in the cosmic web as probed by the Sloan Digital Sky Survey (SDSS) main galaxy sample. This study capitalized on the large-scale structure inference performed by Jasche, Leclercq & Wandelt (2015) using the BORG (Bayesian Origin Reconstruction from Galaxies, Jasche & Wandelt, 2013) algorithm. As the full gravitational model of structure formationcola (COmoving Lagrangian Acceleration, Tassev, Zaldarriaga & Eisenstein, 2013) was used, our approach resulted in the first probabilistic and time-dependent classification of cosmic environments at non-linear scales in physical realizations of the large-scale structure, conducted with real data. Using the Hahn et al. (2007) definition, we obtained three-dimensional, time-dependent maps of the posterior probability for each voxel to belong to a void, sheet, filament or cluster.

These posterior probabilities represent all the available structure type information in the observational data assuming the framework of ΛCDM cosmology. Since the large-scale structure cannot be uniquely determined from observations, uncertainty remains about how to assign each voxel to a particular structure type. The question we address in this letter is how to proceed from the posterior probabilities to a particular choice of assigning a structure type to each voxel. Decision theory (see, for example, Berger, 1985) offers a way forward, since it addresses the general problem of how to choose between different actions under uncertainty. A key ingredient beyond the posterior is the utility function that assigns a quantitative profit to different actions for all possible outcomes of the uncertain quantity. The optimal decision is the one that maximizes the expected utility.

After setting up the problem using our example and briefly recalling the relevant notions of Bayesian decision theory, we will discuss different utility functions and explore the results based on a particular choice.

II. METHOD

The decision problem for structure-type classification can be stated as follows. We have four different web-types which constitute the “space of input features:” \( \{ T_0 = \text{void}, T_1 = \text{sheet}, T_2 = \text{filament}, T_3 = \text{cluster} \} \). We want to either choose one of them, or stay undecided if the data constraints are not sufficient. Therefore our “space of actions” consists of five different elements: \( \{ a_0 = \text{decide void}, a_1 = \text{decide sheet,} a_2 = \text{decide filament}, a_3 = \text{decide cluster} \} \).

---

a)Electronic mail: florent.leclercq@polytechnique.org
“decide cluster,” and \( a_{-1} = \text{“do not decide.”} \) The goal is to write down a decision rule prescribing which action to take based on the posterior information.

Bayesian decision theory states that the action \( a_j \) that should be taken is the one which maximizes the expected utility function (conditional on the data \( d \)), given in this example by

\[
U(a_j | \vec{x}_k | d) = \sum_{i=0}^{3} G(a_j | T_i) \mathcal{P}(T_i | \vec{x}_k | d),
\]

where \( \vec{x}_k \) labels one voxel of the considered domain, \( \mathcal{P}(T_i | \vec{x}_k | d) \) are the posterior probabilities of the different structure types given the data, and \( G(a_j | T_i) \) are the gain functions which state how profitable each action is, given the “true” underlying structure. Formally, \( G \) is a mapping from the space of input features to the space of actions. For our particular problem, it can be thought of as a 5 \( \times \) 4 matrix \( \mathbf{G} \) such that \( G_{ij} \equiv G(a_j | T_i) \), in which case eq. (1) can be rewritten as a linear algebra equation, \( \mathbf{U} = \mathbf{G} \mathbf{P} \) where the 5-vector \( \mathbf{U} \) and the 4-vector \( \mathbf{P} \) contain the elements \( U_j \equiv U(a_j | \vec{x}_k | d) \) and \( P_i \equiv \mathcal{P}(T_i | \vec{x}_k | d) \), respectively.

Let us consider the choice of gain functions. Several choices are possible. For example, the 0/1-gain functions reward a correct decision with 1 for each voxel while an incorrect decision gives 0. This leads to choosing the structure type with the highest posterior probability. While this seems like a reasonable choice, we need to consider that a decision is taken in each voxel, while we are interested in identifying structures as objects that are made of many voxels. For instance, since clusters are far smaller than voids, the \( a \text{ priori} \) probability for a voxel to belong to a cluster is much smaller than for it to belong to a void. To treat different structures on an equal footing, it makes sense to reward the correct choice of structure type \( T_i \) by an amount inversely proportional to the average volume \( V_i \) of one such structure. In the following, we use the prior probability as a proxy for the volume fractions,

\[
P(T_i) \approx \frac{V_i}{V_0 + V_1 + V_2 + V_3}.
\]

We further introduce an overall cost for choosing a structure with respect to remaining undecided, leading to the following specification of the utility,

\[
G(a_j | T_i) = \begin{cases} 
1 - \alpha & \text{if } j \in [0, 3] \text{ and } i = j, \\
-\alpha & \text{if } j \in [0, 3] \text{ and } i \neq j, \\
0 & \text{if } j = -1.
\end{cases}
\]

This choice limits 20 free functions to only one free parameter, \( \alpha \). With this set of gain functions, taking (or not) a decision between structure types can be thought of as choosing to play or not to play a gambling game costing \( \alpha \). Not playing the game, i.e. remaining undecided \( (j = -1) \) is always free \( (G(a_{-1} | T_i) = 0 \text{ for all } i) \). If the gambler decides to play the game, i.e. to take a decision \( (j \in [0, 3]) \), they pay \( \alpha \) but may win a reward, \( \frac{1}{\mathcal{P}(T_i)} \), by betting on the correct underlying structure \( (i = j) \).

In the absence of data, the posterior probabilities in equation (1) are the prior probabilities \( \mathcal{P}(T_i) \) (which are independent of the position \( \vec{x}_k \)), and the utility functions are, for \( j \in [0, 3] \),

\[
U(a_j) = \sum_{i=0}^{3} G(a_j | T_i) \mathcal{P}(T_i)
\]

\[
= \left( \frac{1}{\mathcal{P}(T_j)} - \alpha \right) \mathcal{P}(T_j) - \sum_{i=0}^{3} \alpha \mathcal{P}(T_i)
\]

\[
= 1 - \alpha \left( \mathcal{P}(T_j) + \sum_{i=0}^{3} \mathcal{P}(T_i) \right)
\]

\[
= 1 - \alpha,
\]

and \( U(a_{-1}) = 0 \). (4)

Equations (4) and (5) mean that in the absence of data, this reduces to the roulette game utility function, where, if correctly guessed, \( a \text{ priori} \) unlikely outcomes receive a higher reward, inversely proportional to the fraction of the probability space they occupy. Betting on outcomes according to the prior probability while paying \( \alpha = 1 \) leads to a \textit{fair game} with zero expected net gain. The gambler will always choose to play if the cost per game is \( \alpha \leq 1 \) and will never play if \( \alpha > 1 \).

The posterior probabilities update the prior information in light of the data, providing an advantage to the gambler through privileged information about the outcome. In the presence of informative data, betting on outcomes based on the posterior probabilities will therefore ensure a positive expected net gain and the gambler will choose to play even if \( \alpha > 1 \). Increasing the parameter \( \alpha \) therefore represents a growing aversion for risk and limits the probability of losing. Indeed, for high \( \alpha \), the gambler will only play in cases where the posterior probabilities give sufficient confidence that the game will be won, i.e. that the decision will be correct.

III. MAPS OF STRUCTURE TYPES IN THE SDSS

We applied the above decision rule to the web-type posterior probabilities presented in Leclercq, Jasche & Wandelt (2015), for different values of \( \alpha \geq 1 \) as defined by equation (3). In doing so, we produced various maps of the volume of interest, consisting of the northern galactic cap of the SDSS main galaxy sample and its surroundings. Slices through these three-dimensional maps are...
FIG. 1. Slices through maps of structure types in the late-time large-scale structure, at $a = 1$. The color coding is blue for voids, green for sheets, yellow for filaments and red for clusters. Black corresponds to regions where data constraints are insufficient to take a decision. The parameter $\alpha$, defined by equation (3), quantifies to the risk aversion in the map: $\alpha = 1.0$ corresponds to the most speculative map of the large-scale structure, and maps with $\alpha \geq 1$ are increasingly conservative. These maps are based on the posterior probabilities inferred by Leclercq, Jasche & Wandelt (2015) and on the Bayesian decision rule subject of the present work.

shown in figure 1 for the late-time large-scale structure (at $a = 1$) and in figure 2 for the primordial large-scale structure (at $a = 10^{-3}$).

When the game is fair (namely when $\alpha = 1$), it is always played, i.e. a decision between one of the four structure types is always taken. This results in the speculative map of structure types (top-left panel of figures 1 and 2). There, a decision is taken even in regions that are not constrained by the data (at high redshift or outside of the survey boundaries), based on the prior betting
odds.

By increasing the value of $\alpha > 1$, we demand higher confidence in making the correct decision. This yields increasingly conservative maps of the Sloan volume (see figures 1 and 2). In particular, at high values of $\alpha$, the algorithm takes decisions in the regions where data constraints are strong (see figures 3 and 6 in Leclercq, Jasche & Wandelt, 2015) but often stays undecided in the unobserved regions. It can be observed that even at very high values, $\alpha \gtrsim 3$, a decision for one structure is taken in some unconstrained voxels (typically in favor of the structure for which the reward is the highest: clusters in the final conditions, clusters or voids in the initial conditions). This effect is caused by the limited number of samples used in our analysis. Indeed, due to the finite length of the Markov Chain, the sampled representation of the posterior has not yet fully converged to the true posterior. For this reason, the numerical representation

FIG. 2. Same as figure 1 but for the primordial large-scale structure, at $\alpha = 10^{-3}$. 
of the posterior can be artificially too much displaced from the prior, which results in an incorrect web-type decision. This effect could be mitigated by obtaining more samples in the original BORG analysis (for an increased computational cost); or can be avoided by further increasing $\alpha$, at the expense of also degrading the map in the observed regions. We found the value of $\alpha = 4$ (bottom-right panel of figures 1 and 2) to be the best compromise between a tiny fraction of unobserved voxels in which a decision is taken and remaining information in the volume covered by the data.

As expected, structures for which the prior probabilities are the highest disappear first from the map when one increases $\alpha$: betting on these structures being poorly rewarded, this choice will be avoided in case of high risk aversion. In the final conditions (figure 1), we found that sheets completely disappear for $\alpha \approx 1.68$ and filaments for $\alpha \approx 4.01$. In the initial conditions (figure 2), the critical value is around $\alpha \approx 2.36$ for both sheets and filaments. Note that in the most conservative maps displayed in figures 1 and 2 ($\alpha = 4.0$), the SDSS data provide extremely high evidence for the voids and clusters shown.

As detailed in Jasche, Leclercq & Wandelt (2015), data constraints are propagated by the structure formation model assumed in the inference process (second-order Lagrangian perturbation theory) and therefore radiate out of the SDSS boundaries. For this reason, for moderate values of $\alpha$, web-type classification can be extended beyond the survey boundaries to regions influenced by data. This can be observed in figures 1 and 2, where one can see, for instance, that the shape of voids that intersect the mask is correctly recovered. Similarly, the classification of high-redshift structures confirms that the treatment of selection effects by BORG is correctly propagated to web-type analysis.

**IV. CONCLUSIONS**

In this letter, we proposed a rule for optimal decision making in the context of cosmic web classification. We described the problem setup in Bayesian decision theory and proposed a set of gain functions which permit an interpretation of the problem in the context of game theory. This framework allows to dissect the cosmic web into different elements (voids, sheets, filaments and clusters) given their prior and posterior probabilities and naturally accounts for the strength of data constraints.

As an illustration, we produced three-dimensional templates of structure types with various risk aversion, describing a volume covered by the SDSS main galaxy sample and its surrounding. These maps constitute an efficient statistical summary of the inference results presented in Leclercq, Jasche & Wandelt (2015) for cross-use with other astrophysical and cosmological data sets.

Beyond this specific application, our approach is more generally relevant to the solution of classification problems in the face of uncertainty. For example, the construction of catalogs from astronomical surveys is directly analogous to the problem we describe here: it simultaneously involves a decision about whether or not to include a candidate object and which class label (e.g. star or galaxy) to assign to it.
