Supercritical accretion disks in ultraluminous X-ray sources and SS 433

Sergei Fabrika1,2*, Yoshihiro Ueda3, Alexander Vinokurov1, Olga Sholukhova1 and Megumi Shidatsu3

The black hole mass and accretion rate in ultraluminous X-ray sources (ULXs) in external galaxies, whose X-ray luminosities exceed those of the brightest black holes in our Galaxy by hundreds and thousands of times1,2, is an unsolved problem. Here we report that all ULXs ever spectroscopically observed have almost the same optical spectra, apparently of WNL type (late nitrogen Wolf–Rayet stars) or LBV (luminous blue variables) in their hot state, which are very scarce stellar objects. We show that the spectra do not originate from WNL/LBV-type donors but from very hot winds from the accretion disks with nearly normal hydrogen content, which have similar physical conditions to the stellar winds from these stars. The optical spectra are similar to that of SS 433, the only known supercritical accretor in our Galaxy1, although the ULX spectra indicate a higher wind temperature. Our results suggest that ULXs with X-ray luminosities of $\sim 10^{46}$ erg s$^{-1}$ must constitute a homogeneous class of objects, which most likely have supercritical accretion disks.

ULXs have luminosities exceeding the Eddington limit for a typical stellar-mass black hole1,2, $\sim 2 \times 10^{39}$ erg s$^{-1}$. Despite their importance in understanding the origin of supermassive black holes that reside in most of the present galaxies, several critical questions are still open. What black hole masses do the ULXs contain? Do they possess standard accretion disks? Do they belong to a homogeneous class of objects? The most popular models for the ULXs involve either intermediate mass black holes (IMBH, $10^4-10^5 M_\odot$) with standard accretion disks1 or stellar-mass black holes ($\sim 10 M_\odot$) accreting at super-Eddington rates3. Except for transient ULXs, both scenarios require a donor with a high mass-loss rate in a close binary (such as a massive star and an asymptotic giant branch star), which means a short evolution stage.

Although the X-ray properties of the ULXs are astonishing, it has been impossible, from the X-ray data alone, to distinguish even the main ULX models proposed. Optical spectroscopy may provide us with unique information on the ULXs. Because the ULX optical counterparts are very faint targets ($\sim 22$–$24$ magnitude), however, very deep observations with the largest telescopes are required.

Using the Japanese 8.2 m telescope Subaru, we have obtained highest-quality optical spectra of four nearest, bona fide ULXs that have unambiguous optical counterparts, single star-like objects—Holmberg II X-1, Holmberg IX X-1, NGC 4559 X-7 and NGC 5204 X-1. All details on the observations and data reduction can be found in Supplementary Section 1.

Figure 1 shows the spectra of the ULX optical counterparts (the full range data are given in Supplementary Fig. 1). Main features in all the spectra are the bright He II $\lambda 4686$, and hydrogen H$_\alpha$ and H$_\beta$ emission lines. The lines are obviously broad; the widths range from 500 to 1,500 km s$^{-1}$. In some objects we detect broad He I $\lambda 6678$, 5876 emission lines. The spectra are very blue (Supplementary Fig. 1), in agreement with the photometric results6.

We reveal that the ULX spectra are similar to those of WNL stars, or extreme hot Of supergiants—transition stars, or those of LBVs in their compact hot states$^{7,8}$. All these are massive stars in neighbouring evolutionary stages. This indicates the presence of hot outflow in the binary system: it could be a stellar wind from the donor, an irradiated surface of the accretion disk, or a powerful disk wind. The spectra are also similar to that of SS 433 (ref. 10), the only known supercritical accretor in our Galaxy, a close binary consisting of an A-type supergiant and a stellar-mass black hole. SS 433 apparently exhibits a WNL-type spectrum$^{11}$ because the physical conditions of its disk wind may be similar to those of stellar winds from WNL stars. The impression of the spectral similarity is strengthened because the absolute visual magnitudes of both WNLs and SS 433 are in the same range as in the ULX counterparts$^{4,12}$ (Fig. 2). Note that these WNLs are not WN 5–7 stars, whose spectra are well described with a pure-helium models$^{13}$, but LBV-like WN 9–11 stars, which contain up to 70% hydrogen. Such spectra of high luminosities with prominent He II emission lines have never been observed from any stellar-mass black hole X-ray binaries, except for SS 433 and those having WNL donors.

However, neither very hot WNL nor LBV examples exhibit such strong He II $\lambda 4686$ emission lines relative to the hydrogen lines. If the abundance of hydrogen in the ULX donors were

1Special Astrophysical Observatory, Nizhnij Arkhyz 369167, Russia. 2Kazan Federal University, Kazan 420008, Russia. 3Department of Astronomy, Kyoto University, Kyoto 606-8502, Japan. *e-mail: fabrika@sao.ru
two times smaller from the Solar value, then it could make the He/H ratio five times larger, as observed in these ULX spectra (Supplementary Table 1). This contradicts the non-enhancement of the He I and Pickering He II lines indicating nearly normal abundance of hydrogen. Hence, the wind in the ULXs must be even hotter and more highly ionized than stellar winds in WNL or LBV stars.

All the spectra of the ULXs we obtained are surprisingly similar to one another. The averaged width (FWWH) of the He II line and of H$_\alpha$ are approximately 870 km s$^{-1}$ and 1,000 km s$^{-1}$, respectively. Strikingly, we find that almost all ULX counterparts ever spectroscopically observed exhibit spectra similar to those of WN9–11 stars, particularly in their broad and strong He II emission, including NGC 5408 X-1, NGC 1313 X-2, M81 X-6 and M101 ULX-1 (refs. 13–16). In Fig. 3 we plot the He II and H$_\alpha$ linewidths of our four objects, supplemented with NGC 5408 X-1, which has a simultaneous spectrum including both He II and H$_\alpha$.

We study the spectra of the ULX counterparts in the He II diagram, where the relation between the linewidth and equivalent width of the He II line is plotted (Supplementary Fig. 2). Here the linewidth represents the terminal velocity of a stellar wind, whereas the equivalent width reflects its photosphere temperature and mass-loss rate. We also include hottest transition stars from O2If to WN7/ha (ref. 9), recorded LBV transitions, and SS 433 (ref. 10). The ULXs and SS 433 occupy a region of the hottest transition stars O2If/WN5O3.5If/WN7 stars. However, their behaviour in the He II diagram is nothing like stars. They exhibit night-to-night variability by a factor of 2–3 both in the linewidth and equivalent width. Variability in the radial velocity of the line is also detected, with amplitudes ranging from 100 km s$^{-1}$ in Holmberg IX to 350 km s$^{-1}$ in NGC 5204 (Supplementary Fig. 3).

First, we can exclude the case where these ULXs actually have WN donors and their stellar winds produce the observed optical spectra. Indeed, the rapid variability of the He II linewidth is difficult to explain, because the wind terminal velocity in stars is determined by the surface gravity. A more critical problem is that a WN star means a wind-fed accretion regime, which is not effective. To provide the observed X-ray luminosity, $L_X \approx 10^{36}$ erg s$^{-1}$, one needs an unrealistically powerful wind from the donor if the accretor is a stellar-mass black hole. If the primary star were an intermediate mass black hole (IMBH), then the variability of the donor’s orbital velocity would be much greater than observed (see Supplementary Section 4 for details). Another obvious argument is the high-quality optical spectrum of NGC 7793 P13 indicating a B9la supergiant companion, which itself cannot produce the He II emission line. Therefore, the He II line observed in NGC 7793 P13 must be formed in the second companion, namely, in a photoionized wind from the accretion disk (Supplementary Section 4).

We next consider a possibility that the He II line is formed in the standard accretion disk around a massive black hole. To produce lines in emission, a strong irradiation of the disk surface by the central source is required. The He II lines trace hotter regions located closer to the black hole than the hydrogen lines, and therefore the He II linewidth is expected to be notably larger than that of H$_\alpha$, in a normal geometry. Indeed, broad He II and hydrogen emission lines from the self-irradiated disk are observed in Galactic stellar-mass black hole X-ray binaries in outbursts, such as V404 Cyg (ref. 18), GRO J1655–40 (refs 19, 20) and GX 339–4 (ref. 21). In all these cases, the He II emission lines are exactly broader than the hydrogen lines. These sources did not reach the supercritical regime; the most reliable determination of the distance towards V404 Cyg based on the astrometric VLBI observations indicated that the luminosity was not super-Eddington during its famous 1989 outburst.22 We can interpret that their irradiated disks are not blocked by disk winds completely, and hence we observe the He II emission directly at the disk surface. By contrast, the ULX spectra show that the He II line is narrower than the H$_\alpha$ (Fig. 3) line. It is impossible to explain this fact by irradiated disks unless exotic models are invoked.

We finally examine if the optical spectra of our ULXs can be explained by a supercritical accretion disk (SCAD) with a stellar-mass black hole. Indeed, the only known supercritical accretor SS 433 shows a similar optical spectrum to ours, which is produced by the disk wind from the SCAD (ref. 3). In SS 433 the He II line is narrower than H$_\alpha$ (refs 10, 23). The same is valid in WNL stars and LBV in their hot state.24 This suggests that the He II and H$_\alpha$ lines are formed in different parts of radiatively accelerated disk winds, where more ionized gas located closer to the source has smaller outflow velocities.

In Supplementary Table 1, we present the mean equivalent widths (relative fluxes) of main emission lines in the ULX spectra with respect to SS 433. Although the line fluxes in all our ULXs are very similar, the indicated ionization degrees are higher than that of SS 433; the hydrogen and He II lines are approximately 12 times weaker than those in SS 433, whereas the two observed He I lines are only two times weaker. These testify less dense but hotter disk winds than that in SS 433.
Whereas the luminosity is proportional to the mass accretion rate in standard disks, it is expected to have a logarithmic dependence in SCADs (refs 5,25; Supplementary Section 5), because the excess gas is expelled as a disk wind and the accreted gas is advected with the photon trapping, contributing little to the photon luminosity. Instead, the SCAD luminosity has the same order as the Eddington luminosity, $L_{\text{Edd}} \approx 1.5 \times 10^{39} m_{10} \text{erg s}^{-1}$, where $m_{10}$ is the black hole mass in units of 10 solar masses. The mass accretion rate can provide a factor of several in the logarithmic term. Moreover, the funnel in the SCAD wind will collimate the X-ray radiation to an observer also with a factor of several when observed with an inclination angle smaller than 4050 degrees. Thus, the apparent X-ray luminosity of an ULX with a stellar-mass black hole may well be up to $\sim 10^{41} \text{erg s}^{-1}$. The SCADs are able to account for the huge X-ray luminosities of the ULXs.

The ultraviolet and optical luminosity may depend strongly on the original mass accretion rate $\dot{M}_0$, because these budgets are mainly produced by reprocessing of the strong irradiation from the SCAD's wind (the excess gas). Using simple relations for the SCADs, we find that the optical luminosity of the wind $L_{\text{opt}} \propto \dot{M}_0$ and the wind temperature $T \propto \dot{M}_0^{0.34}$ (see Supplementary Section 5 for a more detailed discussion). Accordingly, we find that the mass accretion rates in the ULXs listed in Fig. 2 may be by a factor of 1.5–6 smaller and their wind temperatures a factor of 1.4–4 higher than those in SS 433. SCAD models can explain both the relative dimness of the ULXs in the optical band and higher ionization states of their disk winds than those of SS 433. Thus, we can interpret that SS 433 is intrinsically the same as ULXs, but an extreme case with a particularly high mass accretion rate, which could explain the presence of its persistent jets.
