ABSTRACT: We investigate the sensitivity of existing LHC searches to the charginos and neutralinos of the MSSM when all the other superpartners are decoupled. In this limit, the underlying parameter space reduces to a simple four-dimensional set \{M_1, M_2, \mu, \tan \beta\}. We examine the constraints placed on this parameter space by a broad range of LHC searches taking into account the full set of relevant production and decay channels. We find that the exclusions implied by these searches exceed existing limits from LEP only for smaller values of the Bino mass \(M_1 \lesssim 150\) GeV. Our results have implications for MSSM dark matter and electroweak baryogenesis.
1 Introduction

Supersymmetry (SUSY) is a well-motivated possibility for new physics, and is one of the main discovery targets of the Large Hadron Collider (LHC). A broad range of SUSY searches have been performed by the ATLAS and CMS collaborations with up to 5 fb$^{-1}$ of data at 7 TeV and 20 fb$^{-1}$ of data at 8 TeV. Despite this great effort, no conclusive signals beyond the predictions of the Standard Model (SM) have been observed so far.

The absence of new signals puts constraints on the masses of the SM superpartners. The strongest bounds apply to the light-flavour squarks and the gluino, and can be as large as $m_{\tilde{q}/\tilde{g}} \gtrsim 1500$ GeV [1, 2]. Limits on stops and sbottoms, which must not be too heavy if they are to protect the naturalness of the weak scale [3], range between $m_{\tilde{t}/\tilde{b}} \gtrsim 200 - 700$ GeV.
depending on how they decay [4–8]. In contrast, superpartners that are uncharged under QCD can often be much lighter while remaining consistent with the current data.

In the present work we study the implications of existing ATLAS and CMS searches on the charginos and neutralinos of the minimal supersymmetric standard model (MSSM). These states, which we will refer to collectively as electroweakinos, are mixtures of the superpartners of the electroweak vector and Higgs bosons, and they take the form of four Majorana-fermion neutralinos $\chi^0_i$ ($i = 1 - 4$ with $|m_i| \leq |m_{i+1}|$) and two Dirac-fermion charginos $\chi^\pm_i$ ($i = 1, 2$ with $|m_1| \leq |m_2|$). All other superpartners, namely the sfermions and the gluino, are assumed to be heavy enough that they can be neglected. Such a spectrum is motivated by the non-observation of squarks or the gluino, and can occur in theories of natural [9–13], or (mini-)split [14–22] supersymmetry. This leads to a relatively simple parameter space of four variables: $\{M_1, M_2, \mu, \tan \beta\}$.

A number of dedicated searches for electroweakinos have been performed by the LHC collaborations [23–25]. These searches focus primarily on final states with multiple leptons, and their results have been interpreted mainly within the context of simplified models [26, 27]. Our work extends these results in three important ways. First, while simplified models are very useful in modelling key features of the production and decay processes, they do not capture the full dynamics of the MSSM. For example, multiple production channels can contribute importantly to the signal, and individual states can have many significant decay paths [28–31]. Second, we investigate the sensitivity to electroweakinos of a much broader range of searches than were considered by the ATLAS and CMS collaborations in this context. And third, we translate the search results into exclusions on $\{M_1, M_2, \mu, \tan \beta\}$, which has only recently been attempted in a limited way by the collaborations. This is useful for comparing with indirect limits on the electroweakinos, such as from flavour mixing and CP violation [32], precision electroweak tests [33], Higgs production and decay rates [34, 35], and cosmological processes like electroweak baryogenesis [36, 37] and dark matter production [38–40].

The implications of LHC searches on electroweakinos have also been the subject of many recent theoretical studies. These analyses often concentrate on specific collider topologies [41–43] or kinematic regimes [44–52], or are focussed on specific dark-matter-motivated scenarios [53–60]. Relative to these studies, we attempt to cover the MSSM parameter space more broadly, and without imposing any restrictions motivated by cosmology. At the same time, our analysis is more focussed on the electroweakinos than the detailed MSSM parameter scans considered in Refs. [61, 62].

The outline of this paper is as follows. After this introduction, we describe the parameter ranges to be studied, their relationship to the spectrum, and their effect on production and decay processes in Section 2. In Section 3 we describe in detail the methods used to reinterpret the LHC results. Next, in Section 4 we give our results in terms of exclusions on the underlying electroweakino parameters. Finally, Section 5 is reserved for our conclusions. Formulas for the relevant masses and couplings are collected in Appendices A and B.
2 Masses and Mixings, Production and Decay

In this work we study the electroweakinos of the MSSM in the limit where all other superpartners (and the additional Higgs bosons) are much heavier. To be concrete, we set the values of the sfermion and gluino soft mass parameters to 2000 GeV together with $m_A = 1500$ GeV, which effectively decouples these states from the LHC searches to be studied. This leaves a four-dimensional parameter space for the electroweakinos consisting of $\{M_1, M_2, \mu, \tan \beta\}$. We take as input the running values of these parameters at the scale $M_S = 2000$ GeV and fix $\tan \beta = 10$. Explicit tree-level expressions for the electroweakino masses and couplings in terms of these parameters are collected in Appendices A and B.

In most of the regions of interest, the diagonal mass-matrix elements, set by $M_1$ and $M_2$ for the gauginos and $\mu$ for the Higgsinos, are significantly larger than the off-diagonal elements, which are proportional to $m_Z$. As a result, the mass eigenstates tend to be closely aligned with the underlying gauge eigenstates unless there is a degeneracy among the diagonal terms. We will therefore speak frequently of Bino-like, Wino-like, and Higgsino-like mass eigenstates. The two Higgsino-like neutralino states coincide with the linear combinations

$$\tilde{H}_\pm^0 = \frac{1}{\sqrt{2}} (\tilde{H}_u^0 \pm \tilde{H}_d^0).$$

Away from degeneracies, the mixing of the Higgsinos $\tilde{H}_a^0$ with the gaugino $\tilde{\lambda}_a$ ($a = 1, 2$) is proportional to $m_Z/|\mu \pm M_a|$, where $M_a$ is the relevant gaugino mass. Note that when $\mu$ and $M_a$ have the same sign, the $\tilde{H}_a^0$ state mixes more strongly with the gaugino than the $\tilde{H}_a^0$ [38]. Mixing between different gaugino-like states requires two small mixing factors and is further suppressed. We will apply these considerations below to explain the relative production and decay rates of the physical chargino and neutralino states.

The relatively small mixing away from degeneracies also motivates us to focus on a specific value of $\tan \beta = 10$. This parameter only enters into the properties of the electroweakinos through the off-diagonal elements of the mixing matrices (and in the direct couplings to the Higgs boson), as described in Appendices A and B. Thus, we expect qualitatively similar results for production rates and decay fractions throughout the range $2 \leq \tan \beta \leq 50$ except where the splitting between two of $M_1, M_2,$ or $\mu$ becomes small.

2.1 LHC Production Rates

In Fig. 1 we show the LHC8 production cross-sections of Bino-like, Wino-like, and Higgsino-like states for $\tan \beta = 10$ with all other parameters taken to be much larger: $m = 2000$ GeV for the sfermions and gluino and $m = 1000$ GeV for the other electroweakino parameters. The physical masses in this limit are given approximately by $M_1, M_2,$ or $\mu$. The neutral Higgsino-like states are labelled in order of increasing mass and correspond to the linear combinations

\footnote{The running of these parameters below this scale is mild, and we find nearly identical results using the same input values defined instead at $M_S = 300$ GeV.}
Figure 1. Production cross sections of the electroweakinos at the LHC with $\sqrt{s} = 8$ TeV in the limit of nearly pure gauge eigenstates. One of $M_1$, $M_2$, or $\mu$ is varied independently with the other values set to 1000 TeV and all other MSSM parameters set to 2000 GeV. The “Mass” label refers to the average mass of the two states being produced. Higgsino states are expressed in terms of $\tilde{H}_0^\pm = (\tilde{H}_0^0 \pm \tilde{H}_1^0)/\sqrt{2}$.

$\tilde{H}_1^0 \sim \tilde{H}_0^0$ and $\tilde{H}_2^0 \sim \tilde{H}_0^0$ defined above. All rates shown in the figure are computed at leading order (LO) with MadGraph 5 [63] and cross-checked in Prospino2.1 [64, 65].

These production cross sections are dominated by processes with intermediate electroweak vector bosons. Both the Winos and Higgsinos couple to vector bosons through their gauge-covariant derivatives. This leads to unsuppressed couplings for $\chi_i^0 \chi_j^\pm W^\mp$ and $\chi_i^\pm \chi_j^0 Z^0$ when both states are pure Wino or pure Higgsino. In contrast, the neutralino couplings $\chi_i^0 \chi_j^0 Z^0$ involve only the Higgsino states, and are also suppressed when the $i = j$ state is Higgsino-like. The absence of a direct Wino coupling to the $Z^0$ arises because $\tilde{W}^0$ has $\bar{t}^3 = Y = 0$. Thus, the production rates of $\tilde{W}^0 \tilde{W}^0$ and $\tilde{B}^0 \tilde{B}^0$ are suppressed since both processes require two Higgsino mixings in the amplitude. The very small $\tilde{H}_1^0 \tilde{H}_1^0$ rates are due to a cancellation in the pure Higgsino limit reflecting the fact that the corresponding mass eigenstates approach Dirac states with only a vector coupling to the $Z^0$ as $m_Z/\mu \to 0$. Production through a $W^\pm$ is generally larger than via the neutral vector bosons.

In Fig. 2 we show the dominant chargino and neutralino production cross sections as a function of the $\mu$ parameter for $\tan \beta = 10$ and fixed $(M_1, M_2) = (200, 300)$ GeV. Similar plots for $(M_1, M_2) = (300, 200)$ GeV are shown in Fig. 3. These figures can be understood in terms of the gauge-eigenstate content of the corresponding mass eigenstates within the six possible hierarchies of $M_1$, $M_2$, and $\mu$.

Of the processes shown in Figs. 2 and 3, the chargino pair production rates in the leftmost panels are the easiest to understand. Here, the $\chi_1^{\pm}$ state is Higgsino-like for $\mu < M_2$ and evolves smoothly into a Wino-like state as $\mu$ increases above $M_2$. The $\chi_1^{\mp} \chi_1^-$ and $\chi_2^{\mp} \chi_2^-$ rates
Figure 2. Leading electroweakino production cross sections as a function of $\mu$ for $M_1 = 200\,\text{GeV}$ and $M_2 = 300\,\text{GeV}$. The leftmost panel shows the chargino-chargino rates, the middle panel shows the dominant neutralino-neutralino rates, and the rightmost panel shows the largest chargino-neutralino rates.

Figure 3. Leading electroweakino production cross sections as a function of $\mu$ for $M_1 = 200\,\text{GeV}$ and $M_2 = 300\,\text{GeV}$. The leftmost panel shows the chargino-chargino rates, the middle panel shows the dominant neutralino-neutralino rates, and the rightmost panel shows the largest chargino-neutralino rates.

follow the expectations for pure states in the appropriate limits, while the rate for $\chi_1^\pm \chi_2^\mp$ is suppressed by the mixing factor it requires.

Neutralino-neutralino production, shown in the middle panels of Figs. 2 and 3, has a slightly more complicated dependence on $\mu$. Away from $\mu \sim M_1, M_2$, the physical mass eigenstates are closely aligned with pure gaugino ($\tilde{W}^0, \tilde{B}^0$) or Higgsino ($\tilde{H}_\pm^0$) states. The hierarchy of production rates can be understood by recalling that neutralino pair production occurs only through the $Z^0 \tilde{H}_+^0 \tilde{H}_-^0$ coupling, and that the $\tilde{H}_+^0$-like state mixes much more readily with gauginos than the $\tilde{H}_-^0$-like state (for $\mu$ and $M_{1,2}$ of the same sign). Thus, the largest production rate occurs for the pair of states coinciding with $\tilde{H}_+^0 \tilde{H}_-^0$, followed by gaugino-$\tilde{H}_1^0$ pairs, and then gaugino-$\tilde{H}_0^0$. The production of gaugino-gauginos or $\tilde{H}_-^0 \tilde{H}_\pm^0$ pairs requires more small mixing factors and is further supressed.

These considerations explain the $\mu$ dependence of neutralino pair production seen in the middle panels of Figs. 2 and 3. The $\tilde{H}_+^0 \tilde{H}_-^0$-like combination is $\chi_1^0 \chi_2^0$ for $\mu < M_\prec \equiv \min\{M_1, M_2\}$, $\chi_2^0 \chi_3^0$ for $M_\prec < \mu < M_\succ \equiv \max\{M_1, M_2\}$, and $\chi_3^0 \chi_4^0$ for $\mu > M_\succ$, and these
are seen to have the largest rates (away from the gaugino masses). A sharp crossover is seen in both panels for the rates of $\tilde{\chi}^0_1\tilde{\chi}^0_2$ and $\chi^0_1\chi^0_3$ at a value of $\mu$ between $M_<$ and $M_>$. For increasing $\mu$ in this range, mixing with the lighter gaugino tends to push the $\tilde{H}^0_1$ mass up relative to $\tilde{H}^0_2$, while mixing with the heavier gaugino tends to push the $\tilde{H}^0_0$ mass down. This leads to a crossover where the $\tilde{H}^0_0$-like state becomes lighter than the $\tilde{H}^0_+$-like state, and the gauge contents of the mass-ordered $\chi^0_2$ and $\chi^0_3$ states are suddenly exchanged with each other. At this point, $\chi^0_1\chi^0_2$ goes from a moderately suppressed gaugino-$\tilde{H}^0_+$ process to a highly suppressed gaugino-$\tilde{H}^0_0$ process, with the opposite occurring for $\chi^0_1\chi^0_3$. A similar crossover is seen for the $\chi^0_2\chi^0_4$ and $\chi^0_3\chi^0_4$ rates. In both cases, the physically relevant quantity is the inclusive neutralino pair production rate, and this varies smoothly with $\mu$.

The rightmost panels of Figs. 2 and 3 show the leading mixed neutralino-chargino production rates. For $\mu < M_2$, the largest cross sections occur for pairs of Higgsino-like states, such as $\chi^+_1\chi^-_1$. As $\mu$ grows larger than $M_2$, there is a smooth transition such that the largest rates occur for pairs of Wino-like states. This corresponds to $\chi^+_1\chi^-_2$ for $M_1 < M_2$ and $\chi^+_1\chi^-_1$ for $M_1 > M_2$.

We have also examined the effects of varying $\tan\beta$ over the range $2 \leq \tan\beta \leq 50$. The dependence of the production cross sections on $\tan\beta$ saturates at larger values, with almost no variation between $\tan\beta = 10$ and $\tan\beta = 50$. For smaller $\tan\beta \sim 2$, the variation can be stronger near a mass degeneracy although the net qualitative effect tends to be mild.

2.2 Decay Branching Fractions

The collider signatures of the electroweakinos depend crucially on how they decay. When all the sfermions are very heavy, the dominant decay channels are

$$
\begin{align*}
\chi^0_i & \rightarrow \chi^\pm_j W^{\mp(*)}, & \chi^0_i & \rightarrow \chi^0_j Z^{(*)}, & \chi^0_i & \rightarrow \chi^0_j h^{0(*)}, \\
\chi^\pm_i & \rightarrow \chi^0_j W^{\pm(*)}, & \chi^\pm_i & \rightarrow \chi^0_j Z^{(*)}, & \chi^\pm_i & \rightarrow \chi^0_j h^{0(*)},
\end{align*}
$$

(2.2)

where $j < i$, and the $W^{\pm}$, $Z^0$, and $h^0$ can be potentially off-shell (as indicated by ($*$)). A loop-mediated decay with a photon is also possible, but we almost always find it to be highly suppressed compared to the channels listed above.

The branching ratios of these decays depend on the gauge-eigenstate content and the mass splittings among the states. In Figs. 4–9 we show the dominant gauge eigenstate components and the leading decay modes for all the neutralino and chargino states in the $\mu$–$M_2$ plane at fixed slices of $M_1 = 20, 100, 180, 260, 340$ GeV with $\tan\beta = 10$. In all cases, the mixing factors and branching ratios were computed with SUSY-HIT 1.3 [66] interfaced with SuSpect 2.41 [67] or SoftSusy 3.3.10 [68]. The upper panels in Figs. 4–9 indicate where the dominant neutralino gauge component is $\tilde{H}^0_1$ (light yellow), $\tilde{H}^0_0$ (light-medium blue), $\tilde{W}^0$ (dark-medium orange), or $\tilde{B}^0$ (dark blue). The variations in shading in these panels show where the fraction of the corresponding state exceeds 50% or 75%. The lower panels of Figs. 6–9 show the dominant decay fractions. The dotted, dot-dashed, and dashed lines in these figures indicate boundaries where the decay modes can occur on shell. While we only
show results for positive values of $\mu$, $M_1$, and $M_2$, we find similar results for other relative signs.

The relative importance of the decay channels shown in Figs. 5–9 can be understood by counting the number of mixings required for each to occur while also taking into account the mass splitting between the initial and final states. Recall that the mixing goes like $m_Z/|M_a \pm \mu|$. As listed in Appendix B, couplings to $W^\pm$ involve Wino-Wino or Higgsino-Higgsino, couplings to $Z^0$ involve only Higgsino-Higgsino, and couplings to $h^0$ involve Higgsino-Wino or Higgsino-Bino. The mass matrices of Appendix A also show that the mass splitting between two relatively pure Wino-like or Higgsino-like states is less than about $m_Z$.

To illustrate this counting, and an additional subtlety associated with it, consider the decay of a Bino-like neutralino into a much lighter Wino-like neutralino or chargino. The gauge modes $\tilde{B}^0 \to W^\pm \tilde{W}^\mp$ and $\tilde{B}^0 \to Z^0 \tilde{W}^0$ both require two mixings in the decay amplitude while $\tilde{B}^0 \to h^0 \tilde{W}^0$ requires only one. While this would seem to favour the Higgs mode when
all three can occur on-shell, the gauge modes are found to be comparable or even more likely. This follows from the Goldstone boson equivalence theorem [69–71]. For large mass splittings $\Delta M$, the decay rates to massive vectors are enhanced by a factor on the order of $(\Delta M/m_Z)^2$ relative to the Higgs channel, and this effectively cancels the additional mixing factor appearing in the amplitudes for the gauge modes [72]. Note that this enhancement is
present only when the initial and final states have a mass splitting parametrically larger than $m_Z$. In particular, no such enhancement occurs for vector boson decays involving Higgsino to Higgsino or Wino to Wino states.

The dominant gauge-eigenstate component of the $\chi_1^0$ neutralino is shown in Fig. 4. Unsurprisingly, it nearly always corresponds to the smallest of the underlying neutralino mass parameters. When the $\chi_1^0$ is mostly Higgsino, it coincides with the $\tilde{H}_0^-$ linear combination.

Figure 8. $\chi_1^0$: Dominant gauge eigenstate content (top) and leading decay modes (bottom) of the $\chi_1^0$ neutralino in the $M_2-\mu$ plane for various slices of $M_1$ and $\tan \beta = 10$. The thick, dashed and dotted lines indicate where the corresponding decays only occur with an off-shell vector boson. Shaded, dash-enclosed regions indicate the boundary of 50% and 75% composition/branching ratio, as noted in the legend.

Figure 9. $\chi_2^\pm$: Dominant gauge eigenstate content (top) and leading decay modes (bottom) of the $\chi_2^\pm$ chargino in the $M_2-\mu$ plane for various slices of $M_1$ and $\tan \beta = 10$. The thick, dashed and dotted lines indicate where the corresponding decays only occur with an off-shell vector boson. Shaded, dash-enclosed regions indicate the boundary of 50% and 75% composition/branching ratio, as noted in the legend.
(for $\mu$, $M_1$, and $M_2$ of the same sign). This state is stable by assumption, and there are no decay modes to be shown.

In Fig. 5, we show the gauge content and the leading decay modes of the lighter chargino, $\chi_1^\pm$. For our choice of positive signs for $\mu$, $M_1$, and $M_2$, we find that it is always the next-to-lightest state in the spectrum. For this reason, the only available decay mode is $\chi_1^\pm \rightarrow W^\pm \chi_1^0$, as can be seen in the lower panels of the figure. The dashed lines in these plots show the boundary between where this decay occurs with the $W^\pm$ off or on shell. This line lies slightly above the contour in Fig. 4 where the lightest $\chi_1^0$ state is Bino-like. When this is not the case, the $\chi_1^\pm$ modes are typically both Wino-like or Higgsino-like and the mass splitting between them is less than $m_W$.

The content and decays of the $\chi_2^0$ neutralino are shown in Fig. 6. Three distinct decay modes are now possible, and the thick dashed and dotted lines in the lower panels illustrate where they can occur on-shell. The decay $\chi_2^0 \rightarrow h^0 \chi_1^0$ is seen to dominate in the upper right corner of these plots when $\chi_2^0$ is Wino- or Higgsino-like and $\chi_1^0$ is Bino-like. The related decay with a $Z^0$ typically has a similar (but smaller) branching in this region. It requires an additional mixing factor relative to the Higgs mode, but can also receive a Goldstone boson enhancement. On the other hand, no such enhancement occurs for $\chi_2^0 \rightarrow W^\mp \chi_1^\pm$ in this region, since both states are close in mass, and the corresponding branching ratio is negligible. Note as well that the Higgs decay dominates only when it is two-body due to the very small width of the Higgs. Vector boson modes are dominant in the rest of the parameter space. When the $\chi_2^0$ state is Wino-like, it tends to be very degenerate with the $\chi_1^\pm$, and so the $Z^0 \chi_1^0$ channel dominates due to the larger available phase space. For a Bino- or Higgsino-like $\chi_2^0$ state, the neutral and charged vector modes tend to have similar branchings, with the Higgs mode contributing at a significant (but sub-leading) level when it can occur on-shell.

The leading components and decay channels of $\chi_3^0$ are shown in Fig. 7. The $\chi_3^0 \rightarrow Z^0 \chi_1^0$ mode dominates when it can occur on-shell but $\chi_3^0 \rightarrow W^\mp \chi_1^\pm$ cannot. This occurs when $|M_1| < |\mu| < |M_2|$. Otherwise, the $W^\mp$ is dominant, although $\chi_3^0 \rightarrow h^0 \chi_1^0$ can be significant as well when it can occur on-shell.

In Fig. 8, we show the content and leading decay modes of the heaviest neutralino $\chi_4^0$. The dominant decay channel is to the kinematically unsuppressed $\chi_4^0 \rightarrow \chi_1^\pm W^\mp$ in the regions where the $\chi_4^0$ has a significant Higgsino or Wino components. For intermediate values of $M_1$, where the LSP is either Wino-like or Higgsino-like and either $\chi_2^0$ or $\chi_3^0$ is Bino-like, the production of $\chi_1^\pm \chi_2^\mp$ is important, as lighter modes will be either suppressed (Bino production) or result in soft decays with low acceptance rates. In the region where $\chi_4^0$ is significantly Bino-like, the branching ratio is split between all unsuppressed modes with one mixing ($\chi_2^\pm W^\mp$, $\chi_1^\pm W^\mp$, $\chi_2^0 Z$), with the largest component (though < 50%) to the Wino-like $\chi_2^\pm$. As the mass of the $\chi_2^\pm$ increases, the $\chi_2^\pm W^\mp$ mode becomes kinematically suppressed, and the Higgsino-like $\chi_2^0 Z^0$ mode dominates over the Higgsino-like $\chi_1^\pm W^\mp$ for the remainder of the region with a Bino-like $\chi_4^0$.

Finally, we show the dominant components and leading decay modes of the heavier chargino $\chi_2^\pm$ in Fig. 9. Production of the $\chi_2^\pm$ is important where the LSP is either Higgsino-
like or Wino-like, since the $\chi_{1}^{\pm}$ state will decay to soft leptons in this region, as indicated in Fig. 5. The decays of the $\chi_{2}^{\pm}$ are relatively uniformly split between $\chi_{1}^{\pm}Z$, $\chi_{2}^{0}W^{\pm}$ and $\chi_{1}^{0}W^{\pm}$, as very little of the parameter space shows branching ratios larger than 50%.

We have also examined the dependence of these decay fractions on $\tan \beta$ in the range $2 \leq \tan \beta \leq 50$. The results throughout this wide range are qualitatively very similar to the $\tan \beta = 10$ case that we have studied in detail.

### 2.3 Implications for LHC Signals

Before turning to a detailed analysis of the sensitivity of LHC searches to electroweakinos, let us briefly emphasize three points that will be important in the analysis to follow. First, production rates tend to be greatest for the lightest pairs of states with significant Higgsino or Wino components, and the subsequent cascade decays are usually fairly short. This motivates searches for relatively simple decay topologies. Second, in a very significant fraction of the parameter space, the leading decay modes occur between states with mass splittings less than $m_Z$ or $m_W$. As a result, the decay products frequently have low $p_T$, and invariant mass pairings that do not reconstruct a resonance (or a kinematic edge). This limits the sensitivity of searches that attempt to reconstruct specific kinematic features characteristic of on-shell vector boson decays or large missing energy. And third, many states are found to have multiple relevant decay modes. This implies that the full inclusive signals of MSSM electroweakinos can be much richer and more complicated than the simplified-model realizations that are frequently applied (e.g. Ref. [24]).

### 3 Methodology of LHC Sensitivity Estimates

We turn next to investigate the sensitivity of ATLAS and CMS searches to neutralinos and charginos. Both collaborations have explored a wide variety of possible SUSY signals, including specific searches geared towards the electroweakinos. In this section we describe the techniques we used to apply these and more general searches to the MSSM. Our results will be presented in the section to follow.

Signal events were generated independently for all 21 possible production pairings using MadGraph5 [63] interfaced with Pythia 6.4 [73]. Hard scattering processes with zero or one additional jets ($pp \to \chi_i\chi_j + \{0,1\}j$) were obtained from MadGraph5 and passed to Pythia 6.4 to be decayed, showered, and hadronized, with the inclusion of MLM matching between additional hard jets and the parton shower [74]. For each MSSM parameter point and each inclusive production channel, 50000 events were generated. These events were then passed to the Delphes 3 detector simulator [75], with triggers, jet reconstruction (anti-kT), and hadronic/leptonic tagging efficiencies modified to match the specifications for each experimental search channel considered. The results from all 21 production channels were combined for each search to obtain the inclusive MSSM signal by weighting each channel by its net cross section after matching and cuts.
The cuts implemented in each search channel in each analysis were reproduced from the information provided by Delphes. All analyses were vetted against cut-flow tables where provided by the experimental groups. To account for pile-up, the $E_T$ values extracted from Delphes were smeared in an additional post-processing step, which was found to be necessary in the vetting process. Specifically, a Gaussian smearing was applied to the Delphes $E_T$ values with a standard deviation of 0.75 times the value given in Ref. [76], where the multiplicative factor compensates for the smearing already present in Delphes. Values of the $m_{T2}$ variable used in some of the analyses were computed using the MT2_Bisect package [78, 79], while the Razor variables of Ref. [80] were calculated using the algorithm provided by the CMS collaboration.

Two superimposed grids of points were generated in the $M_2 - \mu$ plane, with a $5 \times 5$ grid of $M_2$ (100–500 GeV) and $\mu$ (50–500 GeV), and a $4 \times 4$ grid of $M_2$ (140–440 GeV) and $\mu$ (95–433 GeV), for seven slices of $M_1$ (20, 60, 100, 180, 240, 320, 420 GeV). The $4 \times 4$ grid was critical in adding insight into the large regions between the rough $5 \times 5$ grid without significantly increasing the computation time, as would a more populated, uniform grid. The signals calculated at each grid point were then extended to form a uniform $9 \times 9$ grid using linear interpolation of the logarithm of the event rates, following which a three-dimensional order-three polynomial interpolation was performed over the entire $7 \times 9 \times 9$ dataset, again on the logarithm of the event rates. Exclusion regions were then determined from comparison of the calculated number events to the 95% confidence level (C.L.) limit on the number of signal events ($N_i^{95}$). For the ATLAS studies, the $N_i^{95}$ were provided, while for the CMS studies, the $N_i^{95}$ were calculated using the $CL_s$ method [81] with Gaussian-distributed uncertainties as implemented in RooStats [82]. In our analysis, we combine the exclusion regions from each separate signal region in a boolean fashion.

From ATLAS, we investigated the following searches:

- opposite-sign dileptons with $E_T$ and no jets [25]
- trilepton plus $E_T$ [24, 83];
- four or more leptons [84];
- dileptons with razor variables [85]
- hadronic di-$\tau$ plus $E_T$ [86]
- same-sign dileptons plus $E_T$ [87]
- monojet [5, 88].
- jets plus $E_T$ [89];
- disappearing charged tracks [90]

From CMS, we considered the following studies:

---

Ref. [77] found that modifying the Delphes $E_T$ smearing by a post-processed Gaussian smearing with a standard deviation of $\sim 20$ GeV effectively reproduced the smearing effect at LHC8.
• leptons (dilepton, trilepton, multi-lepton) with $E_T$ \[91]\n• chargino and neutralino search using $h \rightarrow b\bar{b}$ decays [23].
• monojet [92].

Many of the LHC searches use similar final states but different specific search strategies. In particular, ATLAS searches tend to focus on a small number of cut regions that are designed to enhance the signal from a specific simplified model, whereas CMS searches tend to be more broadly focused, arranging a grid of cut regions over a larger phase space. As a result, these searches are frequently complementary.

4 Limits from the LHC

Following the methods described above, we have derived exclusions on the parameter space of MSSM charginos and neutralinos using existing LHC searches. Many of the searches we apply were designed to find other superpartners (or forms of new physics), while others have only been used by the collaborations to constrain specific simplified models of the electroweakinos. We find that some of these searches also give new constraints on the more general MSSM electroweakino sector.

The most important LHC exclusions are shown in Figs. 10–13. These correspond to the ATLAS opposite-sign dilepton, trilepton, and four-plus lepton studies, together with the CMS lepton plus $b\bar{b}$ search, and will be discussed in more detail below. The thick black lines in the figures show the boundaries of the combined 95\% confidence level (c.l.) exclusions in the $M_2-\mu$ plane for $\tan\beta = 10$ and several values of $M_1$. The colour shading indicates the number of predicted signal events (after cuts) relative to the number that are excluded by the corresponding experimental analyses. The hatched regions in Figs. 10–13 indicate the 95\% c.l. exclusions from the LEP experiments [93], which are close to $m_{\chi^\pm_1} > 103.4\ GeV$ for $\Delta M = m_{\chi^\pm_1} - m_{\chi_1^0} > 3\ GeV$ or $\Delta M < 0.15\ GeV$ [93] but can fall to as low as 92.4 GeV for mass differences between these boundaries [35, 94]. In these figures we also show contours of constant mass differences $\Delta M$ with thin dashed lines: long dash for $\Delta M = 2m_x$; mid dash for $\Delta M = 15\ GeV$ – where $m_x = m_W$ and $\Delta M = m_{\chi^\pm_1} - m_{\chi_1^0}$ for the lepton analyses in Fig. 10–11, $m_x = m_Z$ with $\Delta M = m_{\chi^0_2} - m_{\chi^0_1}$ in Fig. 12, and $m_x = m_h$ with $\Delta M = m_{\chi^0_2} - m_{\chi^0_1}$ for the Higgs-motivated $b\bar{b}$ analysis in Fig. 13. These lines are useful for understanding constraints, as acceptance rates typically depend on whether decays occur on- or off-shell.

In setting these exclusions, we used the leading-order production cross sections obtained from MadGraph5. These were generally found to lie between the LO and NLO cross sections derived from Prospino2.1 [64, 65], and thus our exclusions are somewhat conservative. However, to illustrate the effects of slightly larger cross sections, we also show with thick solid dashed lines the boundaries of the regions excluded when a $K$-factor of 1.2 is applied to the MadGraph LO signal cross sections. This is typical of the ratio of NLO to LO cross sections computed with Prospino2.1.
\[ M_1 = \begin{array}{cccc} 20 \text{ GeV} & 60 \text{ GeV} & 100 \text{ GeV} & 180 \text{ GeV} \end{array} \]

**Figure 10.** Parameter exclusions from the ATLAS opposite-sign dilepton search of Ref. [25] in the \( M_2 - \mu \) plane for several fixed values of \( M_1 \). The boundaries of the 95\% c.l. excluded regions are denoted by the thick black solid lines (thick black dashed lines) assuming a \( K \) factor of 1.0 (1.2). Colour shading indicates the number of predicted signal events relative to the number excluded by the experimental analysis. The hatched area shows the 95\% c.l. exclusion from LEP. Contours of constant \( \Delta M = m_{\chi^\pm_1} - m_{\chi^0_1} \) are indicated by the thin dashed lines – long dash: \( \Delta M = 2m_W \); mid dash: \( \Delta M = m_W \); short dash: \( \Delta M = 15 \text{ GeV} \).

### 4.1 ATLAS Opposite Sign Dileptons

The ATLAS opposite-sign (OS) dilepton search of Ref. [25] was designed to probe direct slepton and chargino production. Five distinct search regions were considered. All regions had a minimal requirement of two isolated OS leptons with \( p_T > 10 \text{ GeV} \) and \( |\eta| \lesssim 2.4 \), and no jets. Additional requirements were imposed on lepton \( p_T \), \( E_T \), relative lepton flavour, and dileptonic kinematic variables. To suppress backgrounds, an effective \( Z^0 \) veto was imposed on all five regions, either by rejecting events with the leading dilepton invariant mass in the range \(|m_{\ell\ell} - m_Z| < 10 \text{ GeV}\), or by demanding that the leading OS leptons differ in flavour. In four of the five regions, a minimal requirement is imposed on the variable \( m_{T2} > 90 \text{ GeV} \), based on the dilepton system [78, 79]. This is expected to have an endpoint at \( m_W \) for SM backgrounds, while larger values can be obtained for chargino decays with \((m_{\chi^\pm_1} - m_{\chi^0_1}) \gg m_W \). The fifth signal region does not impose a cut on \( m_{T2} \) but suffers from a much larger background rate.

The exclusions derived from this search for general electroweakino parameters are shown in Fig. 10. The strongest bounds are obtained for small values of \( M_1 \), and correspond mostly to the production of Wino- or Higgsino-like \( \chi^\pm_1 \) followed by decays to a Bino-like LSP. Lower \( M_1 \) gives larger mass differences \( \Delta M = m_{\chi^\pm_1} - m_{\chi^0_1} \) for a given value of \( \mu \) or \( M_2 \), which leads to more \( E_T \), larger \( m_{T2} \), and a higher fraction of electroweakino events passing the acceptance cuts. The larger production rate of Winos relative to Higgsinos (see Fig. 1) leads to a stronger exclusion when \( M_2 < \mu \). For \( \mu \sim M_2 \) and \( M_1 = 60 \text{ GeV} \), the exclusions are increased slightly over the \( \mu \gg M_2 \) or \( \mu \ll M_2 \) regions due to contributions from \( \chi^0_2 \chi^0_2 \) production where the decay chain \( \chi^0_2 \to \chi^\pm_1 W^\mp \to \chi^0_1 W^\pm \) and off-shell \( \chi^0_2 \to \chi^0_1 Z^0 \) decays can also contribute to the signal regions.

Very little new exclusion beyond the LEP limit is found for \( M_1 \gtrsim 100 \text{ GeV} \). In this case,

---

3 In contrast to Refs. [78, 79], it is computed here under the assumption of massless decay products.
Figure 11. Parameter exclusions from the ATLAS trilepton search of Ref. [24] in the $M_2 - \mu$ plane for several fixed values of $M_1$. The boundaries of the 95% c.l. excluded regions are denoted by the thick black solid lines (thick black dashed lines) assuming a $K$ factor of 1.0 (1.2). Colour shading indicates the number of predicted signal events relative to the number excluded by the experimental analysis. The hatched area shows the 95% c.l. exclusion from LEP. Contours of constant $\Delta M = m_{\chi^\pm} - m_{\chi^0}$ are indicated by the thin dashed lines – long dash: $\Delta M = 2m_W$; mid dash: $\Delta M = m_W$; short dash: $\Delta M = 15$ GeV.

the LSP need not be Bino-like, and there is the possibility of dominantly Wino-to-Higgsino or Higgsino-to-Wino transitions. However, the LEP chargino bounds force $\mu$ and $M_2$ to each be larger than about 100 GeV. Together with the reduced production rate at higher mass and the need for larger $\Delta M$ to pass the acceptance cuts, there is not enough data to probe this possibility using the dilepton analysis.

4.2 ATLAS Trilepton

The ATLAS trilepton search [24] was designed in part to probe electroweakino production with decays through intermediate sleptons or weak vector bosons. Events with exactly three isolated leptons were selected. One pair must be same-flavour and opposite-sign (SFOS) with $m_{\ell\ell} > 12$ GeV, and events with $b$ jets were vetoed to suppress top backgrounds. Six exclusive search regions were defined with varying (but disjoint) requirements on the invariant mass of the SFOS pairing that is closest to $m_Z$, the $E_T$, the $p_T$ of the lepton not included in the SFOS pairing, and the transverse mass $m_T$ of the unpaired lepton (for some signal regions).

The combined exclusions derived from this analysis are shown in Fig. 11. As in the OS dilepton search discussed above, the strongest limits are found for low $M_1$, where the dominant signal processes involve Wino- or Higgsino-like states decaying to a much lighter Bino-like LSP. Sensitivity is lost at larger $\mu$ or $M_2$ due to reduced production rates and the opening of decays involving Higgs bosons, which produce fewer leptons. Also as above, the sensitivity of this search is greatest for larger $\Delta M$. The interplay between production rates (smaller $M_2$ or $\mu$) and signal acceptance (larger $\Delta M$) can be seen in the $M_1 = 100$ GeV slice. In this slice, disjoint regions are excluded by separate signal regions that are sensitive to either on-shell $Z^0$ decays (isolated exclusion region) or off-shell $Z^0$ decays (bulk exclusion region). The gap between these regions is indicative of the reduced sensitivity of the study to the region where $m_{\chi^0_2} - m_{\chi^0_1} \sim m_Z$, which is also present in the results of [24].
$M_1 = 20$ GeV, $60$ GeV, $100$ GeV, $180$ GeV

**Figure 12.** Parameter exclusions from the ATLAS four-plus lepton search of Ref. [84] in the $M_2 - \mu$ plane for several fixed values of $M_1$. The boundaries of the 95% c.l. excluded regions are denoted by the thick black solid lines (thick black dashed lines) assuming a $K$ factor of 1.0 (1.2). Colour shading indicates the number of predicted signal events relative to the number excluded by the experimental analysis. The hatched area shows the 95% c.l. exclusion from LEP. Contours of constant $\Delta M = m_{\chi_0^0} - m_{\chi_1^0}$ are indicated by the thin dashed lines – long dash: $\Delta M = 2m_Z$; mid dash: $\Delta M = m_Z$; short dash: $\Delta M = 15$ GeV.

For $M_1$ approaching $M_2$ and larger $\mu$, there is a rapid drop in the sensitivity of this search as seen in the upper portions of the $M_1 = 100, 180$ GeV panels of Fig. 11. In this region, the $\chi_1^0$ approaches the $\chi_1^\pm$ state in mass, leading to very soft leptons from $\chi_1^\pm \rightarrow W^\pm \chi_1^0$ decays leading to a low acceptance in the trilepton search channels.

### 4.3 ATLAS Four Lepton

The ATLAS four-lepton search in Ref. [84] was motivated by electroweakino production with decays through intermediate sleptons, R-parity violation, or to a gravitino and $Z^0$ boson. Four or more well-identified leptons were required, with up to one tau included in the count. Five search regions were defined, of which three have a $Z^0$ veto based on the invariant masses of SFOS pairs, with the other two regions demanding that a SFOS pair reconstruct a $Z^0$ to within 10 GeV. Additional requirements were imposed on $E_T$ and $m_{eff}$ (defined to be the scalar sum of jet, lepton, and missing $p_T$).

The exclusions derived from this search are illustrated in Fig. 12. The signal in this case can be generated by $\chi_i^0 \chi_j^0$ production with both $\chi_i^0 \rightarrow Z^{0(*)} \chi_1^0$ and $Z^{0(*)} \rightarrow \ell \bar{\ell}$, or through multistep cascades with $\chi_i^0 \rightarrow W^{\pm(*)} \chi_1^\pm$. We found that the most sensitive signal regions were SRnoZa and SRnoZb defined in Ref. [84]. Recall that neutralino pair production relies on the Higgsino components of the states, and thus this study should be mainly sensitive to smaller values of $\mu$. In addition, $\mu \sim M_2$ results in a number of states with similar masses and significant Higgsino components, which increases the multiplicity of production modes that can contribute to the signal. As for the previous analyses, the sensitivity of this search falls off quickly with increasing $M_1$. 
Figure 13. Parameter exclusions from the CMS lepton plus bottom quarks search of Ref. [23] in the $M_2$–$\mu$ plane for several fixed values of $M_1$. The boundaries of the 95% c.l. excluded regions are denoted by the thick black solid lines (thick black dashed lines) assuming a $K$ factor of 1.0 (1.2). Colour shading indicates the number of predicted signal events relative to the number excluded by the experimental analysis. The hatched area shows the 95% c.l. exclusion from LEP. Contours of constant $\Delta M = m_{\chi_2^0} - m_{\chi_1^0}$ are indicated by the thin dashed lines – long dash: $\Delta M = 2m_h$; mid dash: $\Delta M = m_h$.

4.4 CMS Lepton plus Bottom Quarks

The CMS lepton plus bottom quarks search of Ref. [23] was designed to probe $\chi_2^0 \chi_1^\pm$ production followed by $\chi_2^0 \rightarrow h^0 \chi_1^0$ with $h^0 \rightarrow b\bar{b}$ and $\chi_1^\pm \rightarrow W^{(*)} \chi_1^0$ with $W^{(*)} \rightarrow \ell\nu_\ell$. Events with one lepton, two b-tagged jets, and missing energy were selected. To suppress backgrounds from top quark production, a veto was imposed on additional leptons or jets along with a kinematic cut. Other backgrounds involving a leptonic $W$ were suppressed by demanding $m_T > 100$ GeV for the lepton. The analysis also required a $b\bar{b}$ invariant mass in the range $100$ GeV < $m_{bb}$ < $150$ GeV and applied a variable missing energy cut of $E_T > 100, 125, 150, 175$ GeV.

The sensitivity of this search to the general electroweakino parameter is shown in Fig. 13. In contrast to Ref. [23], we do not find any excluded regions. The difference comes from our use of the computed $\chi_2^0 \rightarrow h^0 \chi_1^0$ branching ratio, whereas the CMS analysis assumes a branching fraction of one. As expected, a significant signal in this channel requires $\Delta M = m_{\chi_2^0} - m_{\chi_1^0} > m_h$, since off-shell decays involving the Higgs are very suppressed by its narrow width. Contours of $\Delta M = m_h$ ($2m_h$) are indicated by mid (long) dashed lines in Fig. 13. For larger $M_1$ values, $\Delta M > m_h$ requires significantly heavy $\mu$ and $M_2$ and thus the sensitivity of current LHC searches drops off quickly.

4.5 Other Searches

In addition to the four channels described above, we have investigated the sensitivity of a number of other LHC searches listed at the end of Sec. 3. These give weaker exclusions, and we will only comment on them briefly.

The CMS collaboration has performed searches for two, three, and four leptons with missing energy in Ref. [91] that are similar to the ATLAS studies considered above. In the CMS studies the signal region is subdivided into a large number of disjoint bins, whereas
ATLAS uses a small number of signal regions geared towards specific decay cascades. Since we do not attempt to combine signal bins and only use boolean exclusions, the ATLAS limits are stronger. ATLAS has also performed a second trilepton analysis in Ref. [83] with slightly different signal requirements than Ref. [24] discussed above. We find similar bounds from Ref. [83], and our trilepton-excluded region matches fairly well with their limit in the $M_2-\mu$ plane with low $M_1$.

We have also examined a broad range of searches that include one or more hard jets and missing energy among the selection requirements. These include the monojet [5, 88, 92] and Razor analyses [85] that have been used to test dark matter production at the LHC [95–98], as well as channels with both hard jets and leptons [87]. The limits obtained from these are weaker than the lepton-centric studies above, with the typically high requirements on jet $p_T$ greatly reducing the electroweakino signal. In particular, we do not find any exclusion beyond the LEP limit from monojet searches, consistent with Refs. [48, 49].

A qualitatively different analysis is the ATLAS search for disappearing charged tracks of Ref. [90]. This search is sensitive to charginos that decay slowly to the lightest neutralino. Such long-lived charginos are expected to occur in the MSSM when $|M_2| \ll |M_1|$, $\mu$, as can occur in anomaly-mediated supersymmetry breaking [99, 100]. In this limit, the tree-level splitting between $\chi_1^\pm$ and $\chi_1^0$ is negligible, and the net mass splitting is dominated by loop effects that give $\Delta m \simeq 160$ MeV [101–103] This leads to a dominant $\chi_1^\pm \rightarrow \pi^- \chi_1^0$ decay with a lifetime on the order of 0.1 ns [101]. For the moderate values of $\mu$ considered here, we find that the mass splitting between $\chi_1^\pm$ and $\chi_1^0$ is larger than 200 MeV, leading to lifetimes below the sensitivity of the ATLAS search. Larger values of $\mu$ than are explored in this study are needed to generate masses with a sufficiently compressed spectrum to be sensitive to bounds from ATLAS, and sufficiently large $M_1$ and $\mu$ can result in sensitivity up to $M_2 \lesssim 260$ GeV.

We also find that the mass splitting can be smaller (or even negative [104]) when some of the mass parameters are negative.

4.6 Combined Exclusions

Putting our results together, we show in Fig. 14 the combined sensitivity of all LHC searches considered in the $M_2-\mu$ plane for $M_1 = 20, 60, 100, 180$ GeV. The thick solid black line shows the 95% c.l. exclusion obtained using LO MadGraph production cross sections, while the dashed black line gives the exclusion when a signal $K$ factor of 1.2 is applied. The hatched region is excluded by LEP analyses. As expected, the excluded region is significant for small $M_1$, but shrinks quickly as $M_1$ is increased.

To investigate the $M_1$ dependence of these exclusions in more detail, we show in Fig. 15 the combined sensitivity of all LHC searches considered in the $M_2-M_1$ plane for $\mu = 162, 275, 388, 478$ GeV. In each of these plots we also indicate the gaugino universality condition of $M_2 \simeq 2M_1$ with a blue dotted line. The excluded region only reaches to $M_1 \sim 100$ GeV. For larger $M_1$ values (and accounting for the LEP limits on charginos), either the mass splittings $\chi_2^0 - \chi_1^0$ and $\chi_1^\pm - \chi_1^0$ become small or the non-LSP states become heavy. Small
Figure 14. Combined exclusions from the LHC analyses discussed in the text in the $M_2$–µ plane for several fixed values of $M_1$. The boundaries of the 95% c.l. excluded regions are denoted by the thick black solid lines (thick black dashed lines) assuming a $K$ factor of 1.0 (1.2). Colour shading indicates the number of predicted signal events relative to the number excluded by the experimental analysis. The hatched area shows the 95% c.l. exclusion from LEP.

mass splittings lead to a poor acceptance by the searches considered, while heavier non-LSP states are produced less frequently.

The excluded regions also shrink as µ becomes large. In particular, the exclusion in the $\mu = 478$ GeV panel of Fig. 15, where the LSP is typically Bino-like and the $\chi_1^\pm$ and $\chi_2^0$ states are Wino-like, is much weaker than the exclusion than the exclusion quoted for a Bino-Wino simplified model in Ref. [24]. In their analysis, they set $\text{BR}(\chi_2^0 \rightarrow Z^0 \chi_1^0) = 1$. In contrast, we find that in this limit the alternative decay mode $\chi_2^0 \rightarrow h^0 \chi_1^0$ can become very significant at large µ. Since the Higgs boson $h^0$ decays only rarely produce more than a single lepton, this strongly suppresses the trilepton signal.

Decreasing µ increases the probability of the $Z^0$ decay, and larger exclusions are found.

Note that in this work we have not examined the detailed dependence of the excluded regions on $\tan \beta$, having fixed its value to $\tan \beta = 10$. However, as discussed previously, we find very similar production cross sections and decay branching fractions for $2 < \tan \beta < 50$. Thus, we expect qualitatively similar results for other values of $\tan \beta$.

5 Conclusions

In this work we have investigated the sensitivity of current LHC searches to the general chargino and neutralino sector of the MSSM in the limit where all the other superpartners are heavy enough to be neglected. This leaves a simple four-dimensional parameter space of \{M_1, M_2, µ, $\tan \beta$\}. We have reinterpreted a diverse set of studies by ATLAS and CMS to derive exclusions on this space.

The greatest LHC sensitivity to general electroweakinos comes from searches requiring multiple leptons and missing energy. This helps to reduce the dominant background to vector diboson production. However, distinguishing the signal from electroweakinos from this remaining background is challenging, especially when the mass spectrum is compressed.

\footnote{We have also checked that our analysis methods give exclusions similar to Ref. [24] when the Higgs decay mode is turned off.}
For this reason, we only find significant parameter exclusions for relatively small values of $M_1 \lesssim 100 \text{GeV}$ with a Bino-like LSP. In this case, signals come from the production of heavier Wino- or Higgsino-like charginos and neutralinos followed by their decays to the LSP, primarily through weak vector bosons.

Despite the limited reach of existing LHC searches, our results show that they have a reasonable acceptance for larger electroweak masses. For this reason, we expect that much larger exclusions will be possible using similar analysis techniques with improved data sets from upcoming LHC runs. Additional data should also allow for the investigation of scenarios with a Wino- or Higgsino-like LSP. Further improvements may also be possible with modified analysis techniques, such as those proposed in Refs. [44, 47, 105, 106].

Our results can be applied to test scenarios where the charginos and neutralinos play an important role. One example is dark matter, where the relic density is very sensitive to the gauge content of the LSP [38–40]. A second case is supersymmetric electroweak baryogenesis, in which the charginos and neutralinos are frequently the dominant new source of CP violation required for the net creation of baryons [107, 108]. In particular, our results suggest that the Bino-driven scenario of Refs. [36, 37, 109] is not significantly constrained by current LHC data.

A Appendix: Mass Matrices and Mixings

The charginos are mixtures of the charged components of the Winos and Higgsinos. Writing
\[
\psi^+ = (-i\tilde{W}_+^+, \tilde{H}_u^+)^t \\
\psi^- = (-i\tilde{W}^-, \tilde{H}_d^-)^t
\]
the corresponding mass term (in two-component notation) is [110, 111]
\[
-L_\pm \supset (\psi^-)^t X \psi^+ + (h.c.) \quad \text{(A.1)}
\]
with
\[
X = \begin{pmatrix}
M_2 & \sqrt{2}s_\beta m_W \\
\sqrt{2}c_\beta m_W & \mu
\end{pmatrix}.
\quad \text{(A.2)}
\]
The matrix \(X\) is not Hermitian in general, so there may not exist a unitary matrix that
diagonalizes it. However, it can always be bi-diagonalized with a pair of unitary matrices \(U\)
and \(V\) such that
\[
V X^\dagger X V^\dagger = U^* X X^\dagger U = \text{diag}(m_{\chi^\pm_1}, m_{\chi^\pm_2}),
\quad \text{(A.3)}
\]
where \(|m_{\chi^\pm_1}| \leq |m_{\chi^\pm_2}|\). In terms of \(U\) and \(V\), the mass and gauge eigenstates are related by
\[
\chi^+_i = V_{ij} \psi^+_j, \quad \chi^-_i = U_{ij} \psi^-_j.
\quad \text{(A.4)}
\]
It is conventional to combine these into four-component Dirac fermions with \(\chi^+_i = (\chi^+_i, \chi^-_i)^t\)
(in an obvious abuse of notation).

For the neutralinos, the mass term in the basis \(\psi^0 = (-i\tilde{B}^0, -i\tilde{W}^0, \tilde{H}_d, \tilde{H}_u)^t\) is [110, 111]
\[
-L \supset \frac{1}{2}(\psi^0)^t Y \psi^0 + (h.c.) \quad \text{(A.5)}
\]
with
\[
Y = \begin{pmatrix}
M_1 & 0 & -c_\beta s_W m_Z & s_\beta s_W m_Z \\
0 & M_2 & c_\beta c_W m_Z & -s_\beta c_W m_Z \\
-c_\beta s_W m_Z & c_\beta c_W m_Z & 0 & -\mu \\
s_\beta s_W m_Z & -s_\beta c_W m_Z & -\mu & 0
\end{pmatrix}.
\quad \text{(A.6)}
\]
This matrix is complex symmetric, and can be diagonalized by a unitary matrix \(N\) such that
\[
N^* Y N^\dagger = \text{diag}(m_{\chi^0_1}, m_{\chi^0_2}, m_{\chi^0_3}, m_{\chi^0_4}),
\quad \text{(A.7)}
\]
where \(|m_{\chi^0_1}| \leq |m_{\chi^0_2}| \leq |m_{\chi^0_3}| \leq |m_{\chi^0_4}|\). The mass eigenstates are related to the gauge
eigenstates via
\[
\chi^0_i = N_{ij} \psi^0_j.
\quad \text{(A.8)}
\]
These two-component fermions can be combined into four-component Majorana spinors $\chi^0_i = (\chi^0_i, (\chi^0_i)^\dagger)^t$ (with another abuse of notation).

B Appendix: Couplings to the Standard Model

For our purposes, we need the couplings of the charginos and neutralinos to the weak vector bosons and the light SM-like Higgs boson.

B.1 Vector Boson Couplings

These can be found in Refs. [110, 112]. We will write everything in four-component notation.

**$W^- \chi^0_i \chi^+_j$**

$$-\mathcal{L} \supset -g W^-_{\mu} \chi^0_i \chi^+_j \gamma^\mu (O^L_{ij} P_L + O^R_{ij} P_R) \chi^+_j + (\text{h.c.}) ,$$  \hspace{1cm} (B.1)

where

$$O^L_{ij} = -\frac{1}{\sqrt{2}} N_{i4} V^*_j + N_{i2} V^*_j ,$$  \hspace{1cm} (B.2)

$$O^R_{ij} = \frac{1}{\sqrt{2}} N^*_{i3} U_j + N^*_{i2} U_j ,$$  \hspace{1cm} (B.3)

with $g$ the $SU(2)_L$ gauge coupling. These terms derive from the $SU(2)_L$-covariant derivatives of the Higgsinos (first terms) and the Wino (second terms).

**$Z^0 \chi^-_i \chi^+_j$**

$$-\mathcal{L} \supset -\tilde{g} Z^0_{\mu} \chi^-_i \gamma^\mu (O'^L_{ij} P_L + O'^R_{ij} P_R) \chi^+_j ,$$  \hspace{1cm} (B.4)

where

$$O'^L_{ij} = -V_{i1} V^*_j + \frac{1}{2} V_{i2} V^*_j + \delta_{ij} s^2_W ,$$  \hspace{1cm} (B.5)

$$O'^R_{ij} = -U_{i1} U_j - \frac{1}{2} U_{i2} U_j + \delta_{ij} s^2_W ,$$  \hspace{1cm} (B.6)

with $\tilde{g} = g/c_W$. These come from the $SU(2)_L \times U(1)_Y$ gauge couplings of the Winos (first terms) and Higgsinos (second terms).

**$Z^0 \chi^0_i \chi^0_j$**

$$-\mathcal{L} \supset -\frac{1}{2} \tilde{g} Z^0_{\mu} \chi^0_i \gamma^\mu (O'^L_{ij} P_L + O'^R_{ij} P_R) \chi^0_j ,$$  \hspace{1cm} (B.7)
where
\[ O_{ij}^{L} = -\frac{1}{2}N_{i\beta}N_{j\beta}^* + \frac{1}{2}N_{i4}N_{j4}^* , \] (B.8)
\[ O_{ij}^{R} = -(O_{ij}^{L})^* , \] (B.9)
with \( \bar{g} = g/c_W \). Note that these couplings come only from the Higgsinos. The Bino has no gauge couplings at all, while the \( \tilde{W}^0 \) has \( t^3 = 0 = Y \) and therefore does not couple to the \( Z^0 \). For \( i = j \), this coupling is purely axial. It also vanishes for \( i = j \) in the limit that \( i \) corresponds to a pure Higgsino state.

\[ \gamma \tilde{\chi}_i^- \chi_j^+ : \]
\[ -\mathcal{L} \supset e A^\mu \tilde{\chi}_i^+ \gamma^\mu \chi_i^- , \] (B.10)
which is purely diagonal and present only for the charginos due to conservation of electric charge. Off-diagonal couplings and couplings to neutralinos can only occur by way of higher-dimensional operators such as the electric and magnetic moment forms.

### B.2 (SM-like) Higgs Couplings

These are listed in Ref. [113]. We will focus exclusively on the couplings to the SM-like Higgs \( h^0 \). The corresponding mixing angles with the \( H_u^0 \) and \( H_d^0 \) gauge eigenstates are
\[ \left( \begin{array}{c} h^0 \\ H^0 \end{array} \right) = \begin{pmatrix} c_\alpha & -s_\alpha \\ s_\alpha & c_\alpha \end{pmatrix} \left( \begin{array}{c} \sqrt{2} (R e H_u^0 - v_u) \\ \sqrt{2} (R e H_d^0 - v_d) \end{array} \right) . \] (B.11)

In the decoupling limit, the couplings of the lighter \( h^0 \) state to matter are identical to the SM. In this limit, the mixing angle reduces to \( \alpha = \beta - \pi/2 \) so that \( c_\alpha = s_\beta \) and \( s_\alpha = -c_\beta \).

\[ h^0 \chi_i^- \chi_j^+ : \]
\[ -\mathcal{L} \supset g h^0 \tilde{\chi}_i^+ \left[ (c_\beta Q_{ji}^* + s_\beta S_{ji}^*) P_L + (c_\beta Q_{ij} + s_\beta S_{ij}) P_R \right] \chi_j^+ \] (B.12)
with
\[ Q_{ij} = \frac{1}{\sqrt{2}} V_{i1} U_{j2} , \] (B.13)
\[ S_{ij} = \frac{1}{\sqrt{2}} V_{i2} U_{j1} . \] (B.14)

These couplings involve one Higgsino component and one Wino component. They come from the \( -i\sqrt{2} \tilde{W}^a H_a^b t^a \tilde{H}_a \) supersymmetrizations of the Higgs boson gauge couplings.
\( h^0 \chi^0_j : \)

\[
- \mathcal{L} \supset g h^0 \chi^0_i \left[ (c_\beta Q''_{ij} - \kappa_\beta S''_{ij}) P_L + (c_\beta Q''_{ij} - \kappa_\beta S''_{ij}) P_R \right] \chi^0_j \tag{B.15}
\]

with

\[
Q''_{ij} = \frac{1}{2} \left[ N_{i3}(N_{j2} - t_W N_{j1}) + N_{j3}(N_{i2} - t_W N_{i1}) \right] \epsilon_i, \tag{B.16}
\]

\[
S''_{ij} = \frac{1}{2} \left[ N_{i4}(N_{j2} - t_W N_{j1}) + N_{j4}(N_{i2} - t_W N_{i1}) \right] \epsilon_i, \tag{B.17}
\]

where \( \epsilon_i \) is the sign of the \( i \)-th mass eigenvalues (for real parameters). As above, these couplings involve one Higgsino component and one Wino or Bino component, and they come from the supersymmetrizations of the Higgs boson gauge couplings.
