ABSTRACT

Context. Up to now, mostly relatively simple molecules have been detected in interstellar diffuse molecular clouds in our galaxy, but more complex species have been reported in the diffuse/translucent medium of a $z = 0.89$ spiral galaxy.

Aims. We aim at searching for complex organic molecules (COMs) in diffuse molecular clouds along the line of sight to Sgr B2(N), taking advantage of the high sensitivity and angular resolution of the Atacama Large Millimeter/submillimeter Array (ALMA).

Methods. We use data acquired as part of the EMoCA survey performed with ALMA. To analyse the absorption features of the molecules detected towards the ultracompact H\textsc{ii} region K4 in Sgr B2(N), we calculate synthetic spectra for these molecules and fit their column densities, line widths, centroid velocities, and excitation temperatures.

Results. We report the detection of CH\textsubscript{3}OH, CH\textsubscript{3}CN, CH\textsubscript{2}CHO, HC\textsubscript{3}N, and NH\textsubscript{3}CHO in Galactic center (GC) diffuse clouds and CH\textsubscript{4}OH and CH\textsubscript{2}CN in a diffuse cloud in the Scutum arm. The chemical composition of one of the diffuse GC clouds is found to be similar to the one of the diffuse/translucent medium of the $z = 0.89$ spiral galaxy.

Conclusions. The chemical processes leading to chemical complexity in the diffuse molecular ISM appear to have remained similar since $z = 0.89$. As proposed in previous studies, the presence of COMs in diffuse molecular clouds may result from a cyclical interstellar process of cloud contraction and expansion between diffuse and dense states.

Key words. ISM: molecules – radio lines: ISM – astrochemistry – ISM: individual objects: Sagittarius B2(N)

1. Introduction

About 200 different molecules have been detected up to now in the interstellar medium (ISM\textsuperscript{[1]}) Carbon-bearing molecules with at least six atoms are commonly referred to as complex organic molecules (COMs). They are detected in dense environments such as cold prestellar cores and hot cores or corinos (Herbst & van Dishoeck 2009). They are usually detected in emission, but several have been detected in absorption, for instance in the envelope of Sgr B2 (Corby et al. 2015). COMs have been detected not only in such dense environments, but also in photodissociation regions (PDRs) like the Horsehead (Guzmán et al. 2014). Here, the strong far-ultraviolet (FUV) radiation seems to play an important role: not only can the COMs survive in such environments, but the UV field also seems to enhance their abundance compared to neighbouring dense clouds (Guzmán et al. 2014).

In addition, several COMs have been detected in absorption in a $z = 0.89$ spiral galaxy, with a chemical composition of this absorber suggesting that the medium is diffuse/translucent (Muller et al. 2011, 2014). Thus, the question arises as to whether COMs also exist in galactic diffuse clouds, in which dust extinction is modest and densities are low. Up to now, mostly fairly simple molecules, such as CN, HCN, CCH, HCO\textsuperscript{+} or c-C\textsubscript{3}H\textsubscript{2}, have been detected in diffuse molecular clouds in our galaxy (e.g. Lucas & Liszt 1997, Godard et al. 2010).

The low densities in diffuse molecular clouds result in low excitation temperatures, close to the temperature of the cosmic microwave background (CMB) radiation, that is, 2.73 K (Greaves et al. 1992). Under these conditions, rotational lines are subthermally excited, very weak, and difficult to detect in emission. Absorption studies have a better sensitivity, but a strong continuum background source is needed. The giant molecular cloud Sagittarius B2 (Sgr B2) fulfills this condition. It is located near the Galactic centre (GC) at a projected distance of 100 pc and a distance of 8.34 ± 0.16 kpc to the sun (Reid et al. 2014).

For our analysis, we use the EMoCA survey that aims at exploring the chemical complexity of the interstellar medium (Belloche et al. 2016). This survey was performed towards the star forming region Sgr B2(N) with the Atacama Large Millimeter/submillimeter Array (ALMA) in Cycles 0 and 1. The spatial resolution of this survey is high enough to resolve the structure of Sgr B2(N) (see Fig. A.1). In this way, we can investigate absorption lines at positions where the continuum is still strong but which are sufficiently far away from the hot cores towards which absorption features are blended with numerous emission lines. The ultracompact H\textsc{ii} region K4 (Gaume et al. 1995) fulfills these requirements. With the high sensitivity of the EMoCA survey we can search for absorption from COMs along the whole 8 kpc-long line of sight to the Galactic centre.

2. Observations and analysis method

We use the EMoCA survey taken with ALMA towards Sgr B2(N). The phase centre (EQJ2000: 17\textdegree47\textquoteleft49, 19.87\textdegree, -28\textdegree22'16") is half way between the two main hot cores N1 and N2 (see Fig. A.1). The survey covers the frequency range from 84.1 to 114.4 GHz with a median
angular resolution of 1″.6. The spectral resolution is 488 kHz or 1.3–1.7 km s\(^{-1}\). The average noise level is ~3 mJy beam\(^{-1}\). The calibration and deconvolution of the data were performed by Belloche et al. (2016). We corrected the spectra for the primary beam attenuation. We use Weeds (Maret et al. 2011) to model the spectra. We assume that all transitions of a molecule have the same excitation temperature and that the beam filling factor is 1. We fit the column density, linewidth, and centroid velocity. We assume the excitation temperature to be equal to the temperature of the CMB (2.73 K) except in the cases where several transitions are detected, for which the temperature is derived from a population diagram.

3. Results

To maximise the sensitivity, we searched for absorption lines of COMs towards the ultracompact \(\text{H~}\eta\) region K4, which is the strongest transition shown in black and the next strongest, if any, in blue. The molecules and rest frequencies of the transitions are given in each panel. The blue spectra are shifted upwards by the value given in parentheses. The synthetic spectra are overlain in magenta. The four dotted lines mark the median centroid in black and the next strongest, if any, in blue. The molecules and rest frequencies of the transitions are given in each panel. The blue spectra are identified lines from 19 di-

Fig. 1. Absorption spectra of simple and complex organic molecules towards the UCH \(\eta\) region K4 in Sgr B2(N). The strongest transition is shown in black and the next strongest, if any, in blue. The molecules and rest frequencies of the transitions are given in each panel. The blue spectra are shifted upwards by the value given in parentheses. The synthetic spectra are overlain in magenta. The four dotted lines mark the median centroid in black and the next strongest, if any, in blue. The molecules and rest frequencies of the transitions are given in each panel. Results

In total, we detected C\(_2\)H\(_2\)-o towards this position. In Table 1, we present results for the complex species: 26.7, 9.4, 3.4, and −2.8 km s\(^{-1}\). The absorption line at 110 km s\(^{-1}\) close to the line of CH\(_3\)CHO at 95963 MHz is another transition of the same molecule. The grey area indicates the velocity range of the Sgr B2 envelope.

The results of the modelling are given in Table 1 for the GC centre clouds and between 3 and 6 km s\(^{-1}\) for the envelope of Sgr B2 and will not be analysed here. The velocity components at around 9.4, 3.4, and −2.8 km s\(^{-1}\) fall roughly in the range of Galactic centre clouds and the component at 26.7 km s\(^{-1}\) lies in the range of the Scutum arm (e.g. Indriolo et al. 2015; Menten et al. 2011 and references therein). Figure A.1 shows as an example the intensity map integrated over the velocity range of the GC diffuse clouds in one of the transitions of NH\(_2\)CHO. The absorption is detected towards K4 only and the spatial extent of the absorption cannot be measured with our data set due to a lack of sensitivity.

To maximise the sensitivity, we searched for absorption lines of COMs towards the ultracompact \(\text{H~}\eta\) region K4, which is the strongest transition shown in black and the next strongest, if any, in blue. The molecules and rest frequencies of the transitions are given in each panel. The blue spectra are shifted upwards by the value given in parentheses. The synthetic spectra are overlain in magenta. The four dotted lines mark the median centroid in black and the next strongest, if any, in blue. The molecules and rest frequencies of the transitions are given in each panel. The blue spectra are identified lines from 19 di-

Results

We plot in Fig. 2a the column densities derived for the GC clouds and Table 2 for the Scutum arm. To calculate the upper limits for \(^{13}\)CH\(_3\)OH we assumed the same velocity and linewidth as for CH\(_3\)OH. To determine the upper limits for the other non-detected molecules we took the median values of the centroid velocities and linewidths as fixed values. The linewidths range between 3 and 6 km s\(^{-1}\) for the GC centre clouds and between 3.5 and 5 km s\(^{-1}\) for the Scutum arm cloud. They fall in the same range as found in other investigations of diffuse molecular clouds along the line of sight to Sgr B2 (e.g. Menten et al. 2011). There are no systematic kinematical differences between the simple molecules H\(^{13}\)CO\(^{+}\) and c-C\(_2\)H\(_2\) and the more complex molecules, so they probably all trace the same regions.

We plot in Fig. 2a, the column densities derived for the diffuse clouds and compare them to the column densities in the \(z = 0.89\) spiral galaxy in front of the QSO PKS 1830–211 (Muller et al. 2011) and S. Muller, priv. comm.), the Horsehead PDR (Pety et al. 2005; Guiocochea et al. 2009; Gratier et al. 2013; Guzmán et al. 2013, 2014 and V. Guzmán, priv. comm.), the hot core Sgr B2(N2) (Belloche et al. 2017, 2016; Muller et al. 2016), and the envelope of the Class 0 protostar NGC 1333-IRAS 2A (Faquet et al. 2015). The HCO\(^{+}\) column densities for the diffuse clouds investigated here are derived from the H\(^{13}\)CO\(^{+}\) column densities assuming an isotopic ratio \(^{12}\)C/\(^{13}\)C equal to 20 for the GC and 40 for the Scutum arm (Milam et al. 2005).
strong for all molecules. The one at $-1.5 \times 10^{-12}$ \text{cm}^{-2}$. The excitation temperatures marked with a star are assumed, the other ones were fitted.

| NH$_2$CHO | <4.0x$10^{12}$ | 26.7            | 4.3             | 4.3             |

Notes. We assumed the same excitation temperatures as in Table 1.

The velocity component at around 3.4 km s$^{-1}$ is relatively strong for all molecules. The one at -2.8 km s$^{-1}$ has comparable column densities, except for HCN, CH$_3$CN, and CH$_2$CN that are not detected. The component at 9.4 km s$^{-1}$ is in general weaker than the previous ones, except for methanol and methyl cyanide for which it is nearly as strong as the first component. CH$_3$CN in the Scutum arm cloud (26.7 km s$^{-1}$) has a similar column density as in the GC clouds, but CH$_3$OH is weaker.

The H$_2$ and H$_2$ column densities of the GC and Scutum-arm diffuse clouds are also plotted in Fig. 2 (see also Table B.2). They were calculated by integrating the column density distributions of Winkel et al. (2017) over velocity ranges equal to the median FWHM of the absorption components in this work. The H$_1$ data have an angular resolution of $\sim 37''$ (Winkel et al. 2017) and the HF data used to determine the H$_2$ column densities $\sim 40''$ (Bergin et al. 2019). The H$_1$ and H$_2$ column densities in the GC clouds are up to one order of magnitude higher than in the Scutum arm. The molecular fraction is 0.70 for the Scutum-arm cloud and 0.4–0.6 for the GC clouds (Table B.2).

Figure 2 shows the abundances relative to methanol. In addition to the sources shown in Fig. 2, the abundances in the translucent cloud CB24 (Turner 1998, Turner et al. 1998, 1999) are also plotted. They correspond to the mean values (and standard deviations as uncertainties) of the different models presented by these authors. Apart from HCN, the chemical composition relative to methanol of the 3.4 km s$^{-1}$ GC diffuse cloud is similar to the one of the $z = 0.89$ spiral galaxy. But no obvious similarity between the COM compositions of these two sources and the other types of sources is apparent in Fig. 2. The diffuse GC clouds, the translucent cloud CB24, the hot core Sgr B2(N2), and the $z = 0.89$ spiral galaxy have similar [CH$_3$CN]/[CH$_3$OH] ratios while the protostellar envelope is nearly two orders of magnitude below. The [HC$_3$N]/[CH$_3$OH] ratio shows a wide spread with the 3.4 km s$^{-1}$ GC component lying four orders of magnitude above the protostellar envelope, and the Horsehead PDR, Sgr B2(N2), CB24, and the $z = 0.89$ spiral galaxy being at a similar intermediate level. Finally all sources except for Sgr B2(N2) have similar [CH$_3$CHO]/[CH$_3$OH] ratios.

4. Discussion

All complex molecules reported in Sect. 3 are detected in the diffuse GC cloud at $\sim 3.4$ km s$^{-1}$. These molecules were also reported by Corby et al. (2015) at a velocity around 0 km s$^{-1}$, but they detected only one velocity component due to their poor spectral resolution (6–10 km s$^{-1}$). While Corby et al. (2015) did not detect complex molecules outside the GC, we report here the detection of CH$_3$OH and CH$_3$CN in a diffuse cloud in the Scutum arm. Figure 2 shows that the non-detection of the other complex species in the Scutum arm does not necessarily reflect a different chemical composition compared to the diffuse GC clouds but may simply be due to a lack of sensitivity.

Methanol’s high abundance ($10^{-9}$–$10^{-8}$) in translucent (and hence perhaps also in diffuse) molecular clouds could be driven by UV photodesorption from dust grains (Turner 1998). This process would not be effective in denser parts of molecular clouds which are mostly shielded against UV radiation. More recently, a process of grain-surface formation and immediate reactive desorption was found to be an important source of gas-phase methanol (Garrod et al. 2007). We find methanol abundances relative to H$_2$ on the order of $10^{-7}$ for the diffuse GC and Scutum-arm clouds (Table B.2), which is surprisingly high, one order of magnitude higher than in translucent clouds (Turner 1998) and dense prestellar cores such as L1544 (6x$10^{-8}$; Vastel et al. 2014).

Although we cannot rule out that the higher UV radiation field in diffuse clouds may enhance the abundance of methanol, it may be that the abundances we obtain are overestimated due to an underestimate of the H$_2$ column density if the clouds are clumpy on a scale intermediate between the resolution of the Herschel HF data (40'') and our ALMA survey (1.6''). CH$_3$CN can be formed effectively in the gas phase without requiring grain-surface formation (Turner et al. 1999, Bergner et al. 2017). CH$_3$CN is enhanced relative to methanol in the Scutum-arm diffuse cloud in comparison to the GC diffuse clouds. This is also the case for the Horsehead PDR. The high abundance of CH$_3$CHO in translucent clouds cannot be explained by gas-phase chemistry only and represents maybe the border to grain chemistry (Turner et al. 1999). This is most likely also true for the diffuse GC clouds, where we detect CH$_3$CHO.

Article number, page 3 of 5
The GC and Scutum-arm clouds have a molecular hydrogen fraction between 0.4 and 0.7, implying that they are indeed diffuse molecular clouds (Snow & McCall 2006). However, the H$_1$ and H$_2$ column densities of the diffuse GC clouds are one order of magnitude higher than those of the Scutum-arm cloud while their molecular fraction is lower (Table B.2), which appears to be contradictory. This may be an indication that the molecular parts of these clouds are clumpy, and in turn that the molecular fraction of the regions where H$_2$ resides is underestimated. This argument supports our previous hypothesis that the methanol abundances derived above are overestimated due to an underestimate of the H$_2$ column densities.

Price et al. (2003) introduced a theory, further tested by Garrod et al. (2005, 2006), in which interstellar clouds, or clumps of translucent medium of molecular clouds may result from a cyclical interstellar process (Menten, K. M., Wyrowski, F., Belloche, A., et al. 2011, A&A, 525, A77). The interferometric Observatory is operated by ESO, AU/INRAO and NAOJ. The interferometric data are available in the ALMA archive at https://almascience.eso.org/aq/

### 5. Conclusions

We report the detection of the (complex) organic molecules CH$_3$OH, CH$_3$CN, CH$_3$CHO, HC$_3$N, and NH$_2$CHO in diffuse GC clouds along the line of sight to Sgr B2(N) and CH$_3$CN in a diffuse cloud of the Scutum arm. The chemical composition of one of the diffuse GC clouds is found to be generally similar to the one of the diffuse/translucent medium of the z = 0.89 spiral galaxy in front of PKS 1830–211, suggesting that the chemical processes leading to chemical complexity have remained similar since z = 0.89. Some differences are seen, however; HCN appears to be more abundant relative to methanol in this diffuse GC cloud compared to the spiral galaxy, while CH$_3$CN is enhanced in the Scutum-arm cloud, like in the Horsehead PDR. The presence of COMs in diffuse molecular clouds may result from a cyclical interstellar process of cloud contraction and expansion between diffuse and dense states (Price et al. 2003, Garrod et al. 2005).

![ALMA continuum map of the Sgr B2(N) region at 85 GHz](image)

**Fig. A.1.** a ALMA continuum map of the Sgr B2(N) region at 85 GHz. The level of the first contour (positive as black solid line and negative as dashed blue line) is 5σ, with σ the rms noise level of 5.4 mJy/beam. The contour step doubles at each contour. b Integrated intensity map of the NH$_2$CHO absorption of the GC diffuse clouds ($V_{\text{LSR}} = -8.9$–6.6 km s$^{-1}$) at 84.5 GHz. The first contour level (positive in white and negative in black) is 5σ, with σ = 17.7 mJy/beam km s$^{-1}$. The contour step doubles at each contour. The grey-scale is indicated at the top. The continuum emission was subtracted. In both panels, the filled ellipse shows the synthesised beam (2.1″ × 1.5″), the black cross indicates the phase centre, the red crosses the positions of the hot cores Sgr B2(N1) and Sgr B2(N2), and the blue cross the position of the ultracompact H II region K4.
