We show that the newly measured branching ratios of vector charmonia (J/ψ, ψ' and ψ(3770)) into γP, where P stands for light pseudoscalar mesons π⁰, η, and η', can be well understood in the framework of vector meson dominance (VMD) in association with the η−η(η') mixings due to the axial gluonic anomaly. These two mechanisms behave differently in J/ψ and ψ' → γP. A coherent understanding of the branching ratio patterns observed in J/ψ(ψ') → γP can be achieved by self-consistently including those transition mechanisms at hadronic level. The branching ratios for ψ(3770) → γP are predicted to be rather small.

I. INTRODUCTION

The recent measurements of the vector charmonium radiative decays to light pseudoscalars, i.e. J/ψ, ψ' and ψ(3770) → γπ⁰, γη and γη', have brought surprises and interests to us. Earlier, the CLEO Collaboration [1] renewed the branching ratios for J/ψ → γπ⁰, γη, γη', and ψ' → γη', which are consistent with the averages from 2008 Particle Data Group [2]. The branching ratio upper limits for ψ' → γπ⁰ and γη were set, which were more than one order of magnitude smaller than that for ψ' → γη'. Meanwhile, the upper limits for ψ(3770) → γP, where P stands for pseudoscalar π⁰, η and η', were set to be about 10⁻⁵ ~ 10⁻⁶. The ψ' radiative decays are also investigated by the BESIII Collaboration with the newly collected 106 million ψ' events, and the results turn out to be tantalizing. It shows that the branching ratios for ψ' → γπ⁰ and γη are only at an order of 10⁻⁶, which are nearly two orders of magnitude smaller than ψ' → γη' [3].

The mysterious aspects somehow are correlated with the J/ψ and ψ' data. It is found that the branching ratio for J/ψ → γπ⁰ is much smaller than those for J/ψ → γη and γη' [2, 4]. This could be a consequence of suppressions of gluon couplings to isovector currents. As a comparison, the observation in ψ' → γP is indeed puzzling. The immediate question is, what drives the difference of decay patterns between J/ψ and ψ'.

In the literature, the radiative decays of the vector charmonia attracted a lot of theoretical efforts. An early study by the QCD sum rules [5] suggested the dominance of short-distance cc annihilations. The gluon and q̄q transition matrix elements were computed by coupling the gluon fields to the pseudoscalar states with which the branching ratio fraction BR(J/ψ → γη')/BR(J/ψ → γη) was satisfactorily described. In Ref. [6], the η, η', and η' mixing angles were extracted and the corresponding mixing angles were accounted for to the correct orders of magnitude. This issue was revisited by Feldmann et al. who proposed to extract the mixing and decay constants on the quark flavor basis [7]. This scheme can be easily extended to accommodate the mixing of η, η' and η'' from which the η-η(η') mixing angles were extracted and turned out to be consistent with those from Refs. [8, 9, 10].

Interestingly, the new data from BESIII for ψ' → γP seem to suggest a deviation from the saturation assumption. It implies that some other mechanisms become important in ψ' → γP, although they may not play a significant role in J/ψ → γP. In this work, we shall show that the vector meson dominance (VMD) model is an ideal framework to make a coherent analysis of the η-η(η') mixing effects and contributions from intermediate vector mesons. We shall show that the ψ' → γP is not saturated by the η-η(η') mixing. Instead, one important mechanism that drives the difference between J/ψ → γP and produces the observed patterns is the sizeable coupling of ψ' → J/ψP.

As follows, we first give a brief introduction to the VMD model and lay out the correlated aspects of the η-η(η') mixings in Sec. II. The detailed analysis, calculation results and discussions will then be presented in Sec. III. A brief summary will be given in Sec. IV.

* E-mail: zhaoq@ihep.ac.cn
In the VMD model (e.g., see review of Refs. 10, 11) the electromagnetic (EM) current can be decomposed into a sum of all neutral vector meson fields including both isospin-0 and isospin-1 components. The leading Vγ* effective coupling can be written as:

\[ \mathcal{L}_{V\gamma} = \sum_{V} \frac{e M_{V}^{2}}{f_{V}} V_{\mu} A^{\mu}, \]

where \( V^{\mu} = (\rho, \omega, f_{0}, J/\psi, ...) \) denotes the vector meson field. The photon-vector-meson coupling constant \( e M_{V}^{2}/f_{V} \) can be extracted from the partial decay width \( \Gamma_{V \to e^{+}e^{-}} \). Neglecting the mass of electron and positron, we have

\[ \frac{e}{f_{V}} = \left[ \frac{3 \Gamma_{V \to e^{+}e^{-}}}{2 \alpha_{e} p_{e}} \right]^{\frac{1}{2}}, \]

where \( p_{e} \) is the electron three-vector momentum in the vector meson rest frame, and \( \alpha_{e} \) is the EM fine-structure constant.

For the decays of \( J/\psi(\psi', \psi(3770)) \to \gamma P \), the VMD contributing diagrams are illustrated in Fig. 1. This classification is based on the photon producing mechanisms and related to the experimental measurements. For instance, Fig. 1(a) identifies such a process that the photon is connected to a hadronic vector meson fields. It requires a sum over all strong transitions of \( J/\psi(\psi', \psi(3770)) \to VP \) channels.

The second process in Fig. 1(b) is via charmonium electromagnetic (EM) annihilations. Such a process generally has small contributions in comparison with the strong transitions. However, it is likely that the EM amplitudes may have significant effects in some exclusive decay channels. In recent series studies 12 14 it shows that in the hadronic decays of \( J/\psi(\psi', \psi(3770)) \to VP \), the short (via three gluon annihilation) and long-distance (Fig. 1(c)) transition amplitudes may have a destructive interfering mode that would efficiently reduce the strong transition amplitudes in some exclusive channels. As a consequence, the EM amplitudes may become compatible with the strong ones, and manifest themselves in experimental observables. This issue is related to the so-called “\( \rho \pi \) puzzle”, which questions why the branching ratio fraction \( BR(\psi(3770))/BR(\gamma \to \rho \pi) \) is so strongly suppressed in comparison with the pQCD expectation values 16 18. A review of this subject and some recent progresses on this problem can be found in the literature 12 14 20.

In the present work, our attention is to understand whether the data for \( J/\psi(\psi', \psi(3770)) \to \gamma P \) are consistent with those for \( J/\psi(\psi', \psi(3770)) \to VP \), and what drives the different radiative decay patterns between \( J/\psi \) and \( \psi' \). We shall adopt the available experimental measurements of \( J/\psi(\psi', \psi(3770)) \to VP \) at this moment. Also, by adopting the experimental data for \( J/\psi(\psi', \psi(3770)) \to VP \), we need not consider the \( \eta - \eta' \) mixing processes since they have been contained in the data for \( J/\psi(\psi', \psi(3770)) \to VP \).

It is worth noting in advance another feature with this classification of Fig. 1. Namely, transitions between vector charmonia may also contribute. For instance, \( \psi' \to J/\psi N \) will contribute to \( \psi' \to \gamma N \). We will show later that this process is essential for understanding the radiative decay patterns for \( J/\psi \) and \( \psi' \to \gamma P \).

Apart from the transitions via Fig. 1, another important transition is via Fig. 2 which corresponds to the \( \eta - \eta' \) mixing due to the axial vector anomaly. Note that the process of Fig. 1(a) with an intermediate charmonium does not overlap with Fig. 2 at the hadronic level. In fact, it is interesting to note their correlated features: i) In both cases, the \( c\bar{c} \) annihilate at short distances. In Fig. 1(a), the vector configuration of \( c\bar{c} \) annihilates into a photon, i.e. \( c\bar{c} \) in a relative S-wave with spin-1, while in Fig. 2 the pseudoscalar \( c\bar{c} \) are in a relative S-wave but with spin-0, and then annihilates into gluons. ii) The process of Fig. 2 is through a typical magnetic dipole (M1) transition of \( J/\psi(\psi', \psi(3770)) \to \gamma N \), which can be regarded as a non-vector-resonance contribution in respect to the VMD scenario.

With the Lagrangian of Eq. 1, the transition amplitude can be expressed as

\[ \mathcal{M}^{VMD}_{\gamma p} = \left( \sum_{\psi} \frac{1}{p_{\psi}^{2} - M_{\psi}^{2}} e M_{\psi}^{2} f_{\psi} g_{\psi VP} \right) \mathcal{F}(p_{\psi}^{2}) \epsilon_{\mu \alpha \beta} P_{\psi}^{\mu} P_{\psi}^{\nu} e_{\gamma}^{\alpha} e_{\gamma}^{\beta}, \]

where \( g_{\psi VP} \) denotes the coupling constants for the hadronic vertex of \( J/\psi(\psi', \psi(3770)) \to VP \), and will be determined by experimental data via

\[ \mathcal{M}_{VP} = g_{\psi VP} \mathcal{F}(p_{\psi}^{2}) \epsilon_{\mu \alpha \beta} P_{\psi}^{\mu} e_{\gamma}^{\nu} e_{\gamma}^{\beta}. \]
We adopt an empirical form for the form factor \( \mathcal{F}(p^2) \)\(^{(5)}\):

\[
\mathcal{F}(p^2) \equiv e^{-p^2/8\beta^2},
\]

where parameter \( \beta \) is in a range of 300 \( \sim \) 500 MeV. This form factor can be interpreted as the wavefunction overlap which would be suppressed in a large recoil momentum region for the final state particles \( \psi' \). The incoherent form factor can also be regarded reasonable in this case. The decay processes are treated in the c.m. frame of the initial meson. Therefore, the anti-symmetric tensor structure of the interactions can always be reduced to a form of \( M_\psi \epsilon_\psi \cdot (p_V \times \epsilon_V) \), which explicitly depends on the three-vector momentum of the final state vector meson. Note that for the anti-symmetric tensor couplings all the contributions to the transition amplitude can be absorbed into the effective coupling form factor. Because of this, it is natural to expect that the form factor would contain information of meson wavefunction overlaps with an explicit three-vector-momentum dependence. In particular, a harmonic oscillator potential for the quark-antiquark system will lead to a form factor similar to Eq. (5).

We shall determine the form factor parameter \( \beta \) combining the data for \( J/\psi(\psi') \rightarrow \gamma P \) and \( \gamma P \). It will then be fixed and adopted for the calculations of other channels. In the transition of Fig. 1(a), the vector meson will carry the momentum of the final state photon \( p_\gamma \).

The transition amplitudes of Fig. 2 can be expressed as

\[
M^{\text{mixing}}_{\gamma P} = \lambda_{\gamma P} g_{\gamma \eta c} \epsilon_\psi \mu \nu \alpha \beta P_\psi \epsilon_\psi P_\gamma \epsilon_\gamma,
\]

where \( \lambda_{\gamma P} \) is the mixing angle between pseudoscalar \( P \) and \( \eta c \). It has been extracted in Ref. \[6\], \( \lambda_{\gamma \eta c} = -4.6 \times 10^{-3} \) and \( \lambda_{\gamma \eta'} c = -1.2 \times 10^{-2} \), which are also obtained by Ref. \[7\]. It should be noted that in the above equation the coupling \( g_{\gamma \eta c} \) is extracted from the data for \( J/\psi(\psi') \rightarrow \gamma \eta c \). The non-local effects from the off-shell \( \eta c \) at the mass of \( \eta(\eta') \) have been included in the mixing angles \[6\]. In the second line, we define a reduced coupling \( \hat{\lambda}_{\gamma P} \equiv \lambda_{\gamma P} g_{\gamma \eta c} / F(p_\gamma^2) \), which can be directly compared with the effective coupling \( (e/f_{\gamma V}) g_{\gamma VP} \) in Eq. (6).

We do not include the \( \eta' c \) mixings with the \( \eta(\eta') \) in \( J/\psi \rightarrow \gamma \eta \) and \( \gamma \eta' \) since their mixing angles are relatively small. Nevertheless, the \( \eta' c \) mixing effects will be further suppressed by the unknown but believed-to-be-small branching ratio for \( \eta' c \rightarrow J/\psi \gamma \).

### III. NUMERICAL RESULTS

#### A. Results from VMD

In Table I the data for 
J/ψ 
ψ' and 
ψ(3770) → VP 
from PDG 2010 are listed. It shows that most of the light VP 
channels have been measured for 
J/ψ 
and 
ψ' 
hadronic decays. In contrast, most of the light VP 
channels for 
ψ(3770) 
are below the experimental precision limit except for 
φη. As mentioned earlier, the 
J/ψ(ψ') → VP 
channels are correlated with the so-called “πτ puzzle” in the literature. However, our attention in the present work is 
different. We shall use the experimental data for 
J/ψ(ψ', 
ψ(3770)) → VP 
as an input to investigate the role played by the VMD mechanisms in the vector charmonium radiative decays. This treatment means that one need not be concerned about the detailed transition mechanisms for 
J/ψ(ψ', 
ψ(3770)) → VP 
at this moment since they all have been contained in the experimental data. We emphasize that this should not be a trivial starting point. Success of such a prescription would help us clarify two major processes in the charmonium radiative decays, i.e. the relative 
S-wave 
cc annihilations would occur either via spin-1 or spin-0 configurations.

In Table I the branching ratios for 
ψ' and 
ψ(3770) → J/ψη and 
J/ψπ⁰ are also listed. As pointed out earlier, these channels are rather important for understanding the observed branching ratio patterns. The effective coupling 
g_{\phi VP} 
in Eqs. 3 and 4 is a scale-independent constant. The data in Table I will allow us to extract 
g_{\phi VP} 
for different VP 
channels in association with the form factor parameter \( \beta \). The overall numerical study suggests that a smaller 
value of \( \beta = 0.3 \) GeV is favored. This is due to that in 
J/ψ(ψ') → γP, the intermediate vector mesons are in a highly 
virtual kinematic region. Part of the off-shell effects would be absorbed into the form factor parameter \( \beta \) as we adopt the 
V → γ* couplings \( e/f_V \) which are determined by data for 
V → e⁺e⁻ .

In Table III we list the joint coupling constants \( (e/f_V)g_{\phi VP} \) for different VP 
channels as a reference. These quantities are the corresponding scale-independent couplings in 
J/ψ(ψ') → γP, and provide an immediate estimate of the relative strengths among those transitions amplitudes that involve different vector mesons. The form factor 
\( F(p^2) = e^{-p^2/\alpha^2} \) with \( \alpha = 0.3 \) GeV will lead to an overall suppression to the vertices. In the light VP sector, the strong \( \rho^0 \) \( \gamma \) coupling accounts for the relatively large contributions from the \( \rho^0 \) mediated transitions.

In the vector-charmonium-mediated channels, the non-negligible coupling of 
g_{\phi J/ψη}, although the decay of 
ψ' → J/ψη is prohibited by the phase space. The influence of 
ψ' → J/ψη' in 
ψ' → γη' should not be neglected and must be included in the amplitude. As we know, the \( \eta \) and \( \eta' \) can be expressed as mixtures of quark flavor singlets:

\[
\begin{align*}
\eta &= \cos \alpha_P n\bar{n} - \sin \alpha_P s\bar{s}, \\
\eta' &= \sin \alpha_P n\bar{n} + \cos \alpha_P s\bar{s},
\end{align*}
\]

(7)
the coupling of and does not include a possible glueball component. If one extends the relative production strength of a \( J/\psi \) appearance in channels’ contributions to \( \gamma P \) the two processes are similar to each other. Namely, we neglect the off-shell effects with the couplings of the glueball component will introduce new parameters. Taking into account that the glueball components within for which different model solutions can be found in the literature [12, 24–26, 28], generally speaking, the introduction of the \( \eta \) and \( \eta' \) mixing to accommodate the glueball \( G \), the coupling of \( g_{\psi^0J/\psi'P} \) can be expressed as

\[
g_{\psi^0J/\psi'P} = g_{\psi^0J/\psi} \left( \frac{\sqrt{2} \sin \alpha_P + R \cos \alpha_P}{\sqrt{2} \cos \alpha_P - R \sin \alpha_P} \right),
\]

where \( R \) describes the SU(3) flavor symmetry breaking. In general, \( R \equiv f_\pi/f_K \approx 0.838 \) is commonly adopted for the relative production strength of an \( s\bar{s} \) to \( q\bar{q} \). The above relation is based on the \( q\bar{q} \) and \( s\bar{s} \) mixing scheme [12, 24–27] and does not include a possible glueball component. If one extends the \( \eta \) and \( \eta' \) mixing to accommodate the glueball \( G \), the coupling of \( g_{\psi^0J/\psi'P} \) can be expressed as

\[
g_{\psi^0J/\psi'P} = g_{\psi^0J/\psi} \left( \frac{\sqrt{2} X_{\psi'P} + R Y_{\psi'P} + G Z_{\psi'}}{\sqrt{2} X_{\eta} + R Y_{\eta} + G Z_{\eta}} \right),
\]

where parameter \( G \) denotes the relative strength of producing the pseudoscalar glueball \( G \) to a light \( q\bar{q} \) component. The general flavor wavefunctions for \( \eta \) and \( \eta' \) are

\[
\eta = X_\eta n\bar{n} + Y_\eta s\bar{s} + Z_\eta G,
\eta' = X_{\eta'} n\bar{n} + Y_{\eta'} s\bar{s} + Z_{\eta'} G,
\]

for which different model solutions can be found in the literature [12, 24, 26, 28]. Generally speaking, the introduction of the glueball component will introduce new parameters. Taking into account that the glueball components within the \( \eta \) and \( \eta' \) are rather small, and Eq. (7) is well established to leading accuracy, we neglect the possible glueball mixing effects in the present analysis.

We adopt the same on-shell couplings of \( g_{J/\psi'P} \) as those extracted in \( \psi' \rightarrow J/\psi P \) since the kinematics for these two processes are similar to each other. Namely, we neglect the off-shell effects with the couplings of \( g_{J/\psi'P} \) in contrast with \( g_{\psi^0J/\psi'P} \).

As listed in Table II it shows that the charmonium poles are one of the most important contributing sources to the \( J/\psi(\psi') \rightarrow \gamma \eta \) and \( \gamma \eta' \), which seems to be slightly out of expectation and has not been addressed before. This feature is explicit for the \( \psi' \) decays since the decay of \( \psi' \rightarrow J/\psi \eta \) is experimentally accessible. In contrast, other \( VP \) channels’ contributions to \( \gamma P \) are rather small due to their relatively small branching ratios. Similar phenomena appear in \( J/\psi \rightarrow VP \) except that the sizeable branching ratio for \( J/\psi \rightarrow \rho \pi \) would also make the \( \rho \pi \) channel an important contributor to the \( \gamma P \) amplitude.

B. Results from $\eta_c-\eta(\eta')$ mixings

In Table III, we list the effective couplings derived from the $\eta_c-\eta(\eta')$ mixings. These values can be directly compared with $(\epsilon_f/\Gamma_f)_{VVP}$ listed in Table III. It shows that in $J/\psi \to \gamma\eta$ and $\gamma\eta'$, the axial-anomaly-driving mixing contributions turn out to be more predominant than the VMD, while in $\psi' \to \gamma P$ the most important contribution is from the $J/\psi$ pole.

We list the individual branching ratios given by the VMD and $\eta_c-\eta(\eta')$ mixings in Table IV as a comparison. Indeed, it shows that the mixing contributions have nearly saturated the branching ratios in $J/\psi \to \gamma\eta$ and $\gamma\eta'$. However, the situation changes in $\psi'$ decays where the VMD mechanisms become more important. An interesting feature is that one in principle needs both to give an overall account of the measured branching ratios.

Note that in Table IV the ranges of uncertainties for the VMD results are given by the experimental errors in Table III.

C. Discussions

To compare with the experimental measurements, we need to add the VMD and $\eta_c-\eta(\eta')$ mixing amplitudes to each other coherently. Taking the advantage of the unique Lorentz structure of the $VVP$ coupling, we can express the total transition amplitude as follows,

$$M_{\text{tot}} = M_{\gamma P}^\text{VMD} + i\delta M_{\gamma P}^\text{mixing},$$

(11)

where $\delta$ is introduced to take into account possible phase differences between these two amplitudes. In the transition processes that we are interested in here, such a phase ambiguity seems inevitable due to a important role played by hadronic transition mechanisms. Since several different hadronic level amplitudes are involved in $M_{\gamma P}^\text{VMD}$, it is not a necessity that $M_{\gamma P}^\text{VMD}$ and $M_{\gamma P}^\text{mixing}$ should share the same phase angle for different pseudoscalar channels. We expect that the experimental data would provide a constraint on it.

In Fig. 3, we plot the $\delta$-dependence of the branching ratios in comparison with the PDG2010 averages and new experimental data from BESIII. It shows that in the two decays, $J/\psi \to \gamma\eta$ and $\psi' \to \gamma\eta'$, the transition amplitudes of the VMD and $\eta_c-\eta(\eta')$ mixings are well in phase. In contrast, they seem to be out of phase in $\psi' \to \gamma\eta$, although the experimental uncertainties are quite large. The central value of the data can be best accounted for at $\delta \simeq 140^\circ$ or $220^\circ$. More complex phases appear in $J/\psi \to \gamma\eta'$, although the dominant contributions are from the axial gluonic anomaly. In this case, the phase angle $\delta = 80^\circ$ or $280^\circ$ are favored. It should be mentioned that in a recent paper by BESIII, a smaller branching ratio for $J/\psi \to \gamma\eta'$ is reported, i.e. $BR(J/\psi \to \gamma\eta') = (4.86 \pm 0.03 \pm 0.24) \times 10^{-3}$.

In Table V, we list the coherent results for the branching ratios $BR(J/\psi \to \gamma P)$ and $BR(\psi' \to \gamma P)$ in comparison with the data again. The phase angles are fixed as shown in Fig. 3 with the best description of the central value of the data. Again, the theoretical uncertainties due to adopting the data for $J/\psi(\psi') \to VP$ are included.
We also include the $\psi(3770) \rightarrow \gamma P$ as a prediction of the VMD mechanism. The predicted branching ratios are all small. The $\eta_c$ mixing contributions are not included here due to lack of data. Also, most of the light vector meson contributions to the $\psi(3770)$ radiative decays are rather small and unavailable. Thus, the predicted branching ratios are actually given by the $J/\psi$ pole in the VMD model. Given the same statistics for $\psi(3770)$ as the $\psi'$ from BESIII, the accessible channel would be $\psi(3770) \rightarrow \gamma \eta'$. Experimental examination of the predicted pattern in Table V would be an interesting test of the VMD mechanisms proposed in this work.

In general, the results fit the observed branching ratio pattern very well, except that the branching ratio for $\psi' \rightarrow \gamma \pi^0$ seems to have some discrepancies. It might be a sign that other non-VMD mechanisms may also play a role. For $J/\psi \rightarrow \gamma \pi^0$, the dominance of $J/\psi \rightarrow \rho^0 \pi^0$ can naturally account for the data. It should be mentioned that Ref. [31] also confirms the VMD contributions via the $\rho^0 \pi^0$ channel to $J/\psi \rightarrow \gamma \pi^0$.
Our investigation suggests the importance of a coherent treatment for the VMD mechanism and $\eta \to \gamma \eta'$ mixings. Note that the charmonium pole contribution has not been included by the previous studies [2]-[9, 24, 28]. Meanwhile, an understanding of why the VMD and axial gluonic anomaly mechanisms play different roles in $J/\psi$ and $\psi'$ decays would be essentially important. The following points may help to clarify this question:

i) As mentioned earlier, there are some interesting correspondences between the axial gluonic anomaly and VMD in this case. In the axial gluonic anomaly transitions the $cc$ couple to a photon, and radiate two soft gluons which can couple to pseudoscalar states. The situation changes in $\psi'$ to $\eta \eta'$. The VMD transition will be dominated by the $\psi' \gamma$ coupling since as the first radial excited state the wavefunction of $\psi'$ at the origin is smaller than that of $J/\psi$. In contrast, the axial-gluonic-anomaly-driving $\eta_c - \eta'$ mixings will occur via $J/\psi \to \gamma \eta_c \to \gamma \eta'$, where the first step is a typical EM M1 transition between two ground charmonium states. It is allowed by the quantum transition selection rule at leading order.

The above qualitative argument explains why the VMD mechanism and axial gluonic anomaly play different roles in $J/\psi$ and $\psi'$ decays, respectively, as manifested by the calculation. In particular, it shows that both mechanisms are crucial for our understanding of the observed branching ratio patterns.

The successful account of the observed branching ratio patterns for $J/\psi(\psi') \to \gamma P$ in the VMD model has an important implication of the hadronic decay mechanisms for $J/\psi(\psi') \to VP$. It shows that the “puzzling” radiative decay patterns in $J/\psi(\psi') \to \gamma P$ have direct connections with the hadronic decay mechanisms, i.e. $J/\psi(\psi') \to VP$, instead of some other abnormal processes. As a consequence, it will guide our further investigations of the transitions of $J/\psi(\psi') \to VP$, and impose constraints on processes such as illustrated by Fig. 1. For instance, the hadronic part of Fig. 1(c) is found to be an important non-perturbative QCD mechanism that contributes predominantly in $\psi' \to J/\psi \eta$ and $J/\psi \pi^0$ [31, 32]. As pointed out recently in a series of papers on the subject of non-perturbative transition mechanisms in charmonium decays [14, 20, 31, 57], such intermediate meson loop transitions would be an natural mechanism for evading the pQCD helicity selection rule and explaining the “$\rho \pi$ puzzle” in $J/\psi(\psi') \to VP$.

IV. SUMMARY

In brief, with the available data for $J/\psi(\psi') \to VP$, we show that the VMD model is still useful for our understanding of the newly measured branching ratios for $J/\psi(\psi') \to \gamma P$ in association with the $\eta_c - \eta'$ mixings via the axial gluonic anomaly. Importance of such a contribution has not been recognized before. In particular, we stress that the intermediate vector charmonia can have significant contributions via e.g. $\psi' \to J/\psi \eta \to \gamma \eta$. We show that these two mechanisms behave differently in $J/\psi$ and $\psi' \to \gamma P$, and can be understood by state transition selection rules. We also emphasize that the consistency between $J/\psi(\psi') \to \gamma P$ and $VP$ demonstrated in this work would impose important constraints on the non-pQCD mechanisms in $J/\psi(\psi') \to VP$. It would be useful for our final understanding of the long-standing “$\rho \pi$ puzzle” in $J/\psi(\psi') \to VP$.
