Abstract

In this paper we propose an enhanced version of the residual sub-sampling method (RSM) in [9] for adaptive interpolation by radial basis functions (RBFs). More precisely, we introduce in the context of sub-sampling methods a maximum profile likelihood estimation (MPLE) criterion for the optimal selection of the RBF shape parameter. This choice is completely automatic, provides highly reliable and accurate results for any RBFs, and, unlike the original RSM, guarantees that the RBF interpolant exists uniquely. The efficacy of this new method, called MPLE-RSM, is tested by numerical experiments on some 1D and 2D benchmark target functions.

Keywords: meshless interpolation, radial basis functions, adaptive algorithms, residual sub-sampling methods, optimal shape parameters

2020 MSC: 65D05, 65D12, 65D15

1. Introduction

In [9] the residual sub-sampling method (RSM) is proposed. This adaptive scheme is based on radial basis function (RBF) interpolation. It is used to approximate the unknown target function on uniformly distributed points, and then the residual is evaluated at halfway points. The latter are added to the point set when the residual is over a prescribed refinement threshold, whereas they are removed from that set when it is under a predefined coarsening threshold. Further, the interpolating process is characterized by a variable selection of the multiquadric RBF shape parameter. The user assigns an initial value of such parameter, and then it is updated point-by-point based on node spacing. A similar strategy has also been implemented in [22], though in both cases the change of the shape parameter at each point does not guarantee the invertibility of the interpolation matrix. Indeed, as known in literature and observed in [9], the use of node-dependent shape parameters breaks the symmetry of the interpolation matrix as well as the proof of its nonsingularity.

While several adaptive schemes exist for solving boundary value problems or partial differential equations (see e.g. [1 6 10 17]), the problem of constructing adaptive algorithms in RBF interpolation has been considered only in part (see [1 2 6 14 15 22] and references therein). This fact motivates us to enhance further the current state of the art on the topic.

In this paper we present a modification of the original RSM in [9], proposing an optimal selection of the shape parameter via a \textit{maximum profile likelihood estimation} (MPLE) criterion, which relies on a solid stochastic framework (see [12 19 24]). This choice is totally automatic, i.e., user’s action is not required, either initially, but a single (near-optimal) parameter is determined for every node. In this way, the interpolation problem is well-posed and hence the RBF (or kernel) interpolant exists uniquely, naturally

provided that the kernel matrix is positive definite (see e.g. \cite{13}). Moreover, the use of MPLE technique is particularly useful to take under control the ill-conditioning of the interpolation matrix when in the iterative/adaptive method the number of interpolation points grows. Therefore, unlike the previous methods discussed in \cite{9, 16, 22}, this modification of the RSM, called MPLE-RSM, provides a twofold benefit. As a matter of fact, it enables to solve the above mentioned issue of nonsingularity of the interpolation matrix, and give “good” predictions of the shape parameter for any kernel avoiding user’s tuning each time. As our numerical results show, application of the MPLE criterion generally results in an adaptive interpolation scheme more efficient than the original RSM, also reducing the number of points needed for satisfying the expected precision. The improved method is tested by taking some 1D and 2D benchmark target functions.

The paper is organized as follows. In Section 2 we introduce the kernel based interpolation. Section 3 presents the MPLE strategy to determine the optimal shape parameter in the improved RSM. In Section 4 we describe the adaptive algorithm. In Section 5 we show some numerical results, illustrating the performance of the MPLE-RSM and comparing the latter with the basic RSM discussed in \cite{9}. Section 6 contains conclusions.

2. Kernel based interpolation

Kernel based methods are powerful tools for data interpolation. In this section we introduce basic notations and results for kernel based interpolation. For further theoretical background and other details, we refer the reader to \cite{3, 13, 21}.

Given a compact domain Ω ⊂ ℝ^d, we assume that the N distinct data points (or nodes) are defined by the set \( X = \{ x_i \}_{i=1}^N \subseteq \Omega \). The data values associated with \( x_i \), \( i = 1, \ldots, N \), are given by \( y_i = f(x_i) \in \mathbb{R} \), where the latter are obtained by sampling some function \( f : \Omega \to \mathbb{R} \). Thus, we want to find a function \( s_X : \Omega \to \mathbb{R} \) satisfying the interpolation conditions
\[
s_X(x_i) = y_i, \quad i = 1, \ldots, N. \tag{1}
\]

We express the interpolant \( s_X \) in terms of a kernel \( \Phi : \Omega \times \Omega \to \mathbb{R} \), i.e.
\[
s_X(x) = \sum_{j=1}^N c_j \Phi(x, x_j), \quad x \in \Omega. \tag{2}
\]

If the kernel \( \Phi \) is symmetric and strictly positive definite (SPD), the interpolation matrix \( A = (A_{ij}) \) with the entries \( A_{ij} = \Phi(x_i, x_j) \), \( i, j = 1, \ldots, N \), is positive definite for any set \( X \). The coefficients \( c_j \) in \( 2 \) are uniquely determined by enforcing the interpolation conditions \( 1 \) and can be obtained by solving the symmetric linear system
\[
Ac = y, \tag{3}
\]
where \( c = (c_1, \ldots, c_N)^T \) and \( y = (y_1, \ldots, y_N)^T \).

Associated with the kernel \( \Phi \) in \( 2 \) we may define a SPD RBF \( \phi : \mathbb{R}_0^+ \to \mathbb{R} \) such that
\[
\Phi(x, x_j) = \phi_\varepsilon(||x - x_j||_2) = \phi(\varepsilon||x - x_j||_2), \quad \forall x, x_j \in \Omega,
\]
where \( \varepsilon > 0 \) is the so-called shape parameter, and \( || \cdot ||_2 \) denotes the Euclidean norm on \( \mathbb{R}^d \). Moreover, we know that the choice of a “good” value of \( \varepsilon \) is generally a crucial task for kernel based interpolation, but at the same time also a big issue (see e.g. \cite{8, 16, 13, Chapter 14}). Some examples of popular SPD RBFs (or radial kernels) together with their smoothness degrees and abbreviations are listed as follows (see
When solving the linear system $[A]$, the solution is often very sensitive to changes in the data. Moreover, such sensitivity is influenced by the choice of the shape parameter $\varepsilon$. A criterion for measuring the numerical stability of a kernel method is to compute the condition number of the interpolation matrix $A$. Hence, since the kernel $\Phi$ is symmetric and SPD, the condition number of $A$ is defined as follows:

$$\kappa(A) = \|A\|_2 \|A^{-1}\|_2 = \frac{\lambda_{\text{max}}}{\lambda_{\text{min}}}$$

where $\lambda_{\text{max}}$ and $\lambda_{\text{min}}$ are the largest and smallest eigenvalues of $A$.

Furthermore, for the kernel $\Phi$ there exists the so-called native space, which is a Hilbert space $N_{\Phi}(\Omega)$ with inner product $(\cdot, \cdot)_{N_{\Phi}(\Omega)}$ in which the kernel $\Phi$ is reproducing, i.e., for any $f \in N_{\Phi}(\Omega)$ we have the identity $f(x) = (f, \Phi(\cdot, x))_{N_{\Phi}(\Omega)}$, with $x \in \Omega$. Then, if we introduce a pre-Hilbert space $H_{\Phi}(\Omega) = \text{span}\{\Phi(\cdot, x), \ x \in \Omega\}$, with reproducing kernel $\Phi$ and equipped with the bilinear form $(\cdot, \cdot)_{H_{\Phi}(\Omega)}$, the native space $N_{\Phi}(\Omega)$ of $\Phi$ is its completion with respect to the norm $||\cdot||_{H_{\Phi}(\Omega)} = \sqrt{(\cdot, \cdot)_{H_{\Phi}(\Omega)}}$. In particular, for all $f \in H_{\Phi}(\Omega)$ we have $||f||_{N_{\Phi}(\Omega)} = ||f||_{H_{\Phi}(\Omega)}$ (see [21]). Now, we can thus provide an error bound in terms of the well-known power function $P_{\Phi, X}$ (see e.g. [11, Theorem 14.2]):

**Theorem 2.1.** Let $\Omega \subseteq \mathbb{R}^d$, $\Phi \in C(\Omega \times \Omega)$ be strictly positive definite on $\mathbb{R}^d$, and suppose that $X = \{x_i\}_{i=1}^N$ has distinct points. Then, for all $f \in N_{\Phi}(\Omega)$, we have

$$|f(x) - s_X(x)| \leq P_{\Phi, X}(x)||f||_{N_{\Phi}(\Omega)}, \quad x \in \Omega.$$  

The generic error estimate of Theorem 2.1 can further be refined as shown in [11, Theorem 14.5]:

**Theorem 2.2.** Let $\Omega \subseteq \mathbb{R}^d$ be bounded and satisfy an interior cone condition. Suppose that $\Phi \in C^{2k}(\Omega \times \Omega)$ is symmetric and strictly positive definite. Then, for all $f \in N_{\Phi}(\Omega)$, there exist constants $h_0$, $C > 0$ (independent of $x$, $f$ and $\Phi$) such that

$$|f(x) - s_X(x)| \leq C h_{X, \Omega}^k \sqrt{C_{\Phi}(x)} ||f||_{N_{\Phi}(\Omega)},$$

provided $h_{X, \Omega} \leq h_0$. Here

$$C_{\Phi}(x) = \max_{|\beta|=2k} \max_{w, z \in \Omega \cap B(x, c_2 h_{X, \Omega})} \left| D^\beta \Phi(w, z) \right|$$

with $B(x, c_2 h_{X, \Omega})$ denoting the ball of radius $c_2 h_{X, \Omega}$ centred at $x$, and $h_{X, \Omega}$ being the fill distance

$$h_{X, \Omega} = \sup_{x \in \Omega} \min_{x_j \in X} ||x - x_j||_2.$$  

Theorem 2.2 states that interpolation with a $C^{2k}$ smooth kernel $\Phi$ has approximation order $k$. Thus, we deduce that: (i) for $C^\infty$ SPD kernels, the approximation order $k$ is arbitrarily high; (ii) for SPD kernels with limited smoothness, the approximation order is limited by the smoothness of the kernel. For more refined error estimates, we refer the reader to the monograph [21].
3. MPL criterion for near-optimal choice of the shape parameter

In Section 2 we compute the interpolant \( s_X \) in (2) by solving the linear system (3), where the kernel matrix \( A \) is symmetric and positive definite. However, by the uncertainty or trade-off principle, we know that using a standard RBF one cannot have high accuracy and stability at the same time. In fact, when the best level of accuracy is typically achieved, i.e., in the flat limit \( \varepsilon \to 0 \), the interpolation matrix may be very ill-conditioned. It is therefore important to study a criterion that enables us to make reliable \( \varepsilon \)-predictions. In this work we discuss the MPL criterion, which will apply in the residual sub-sampling interpolation method.

### 3.1. Gaussian random field and density function

The MPL criterion is mainly based on a stochastic framework, and so the concept of Gaussian random field (or Gaussian process) is introduced [13].

**Definition 3.1.** The random field \( Y = \{Y_x \in \Omega \} \) is called a Gaussian random field if, for any given choice of finitely many distinct points \( X = \{x_i\}_{i=1}^N \subseteq \Omega \), the vector of random variable \( Y = (Y_{x_1}, \ldots, Y_{x_N})^T \) has a multivariate normal distribution with mean vector \( \mu = E[Y] \) and covariance matrix \( \sigma^2 A = (Cov(Y_{x_i}, Y_{x_j}))_{i,j=1}^N \), where \( \sigma^2 \) is the process variance.

In terms of notation we write \( Y \sim N(\mu, \sigma^2 A) \) to denote that \( Y \) is a vector of Gaussian random variables, or \( Y \sim N(\mu, \sigma^2 A) \) to indicate that \( Y \) is a Gaussian random field.

The multivariate normal distribution has the density function

\[
p_Y(y) = \frac{1}{\sqrt{(2\pi\sigma^2)^N \det A}} \exp \left[ -\frac{1}{2\sigma^2} (y - \mu)^T A^{-1} (y - \mu) \right].
\]

In the stochastic setting the process variance plays an important role, for instance, in the formulation of the kriging variance and in parameter estimation. In fact, it does not affect the kernel interpolant (or kriging predictor, as known in this context), but this influences its variance and as a consequence the maximum likelihood estimation in the choice of the optimal value of \( \varepsilon \).

Now, the parameters \( \varepsilon \) and \( \sigma^2 \) might be viewed as draws from random variables \( \Sigma \) and \( \Sigma \), respectively, with unknown distributions. By studying the joint distribution \( (\Sigma, \varepsilon, Y) \), the kernel parametrization would require to optimize for both \( \sigma^2 \) and \( \varepsilon \) maximizing \( p_{\varepsilon, \Sigma} Y(\sigma^2, \varepsilon | Y = y) \), which we can suppose proportional to the density function

\[
p_{Y|\Sigma, \varepsilon}(y|\Sigma = \sigma^2, \varepsilon = \varepsilon) = \frac{1}{\sqrt{(2\pi\sigma^2)^N \det A}} \exp \left[ -\frac{1}{2\sigma^2} y^T A^{-1} y \right].
\]

where though \( \varepsilon \) does not explicitly appear on the right hand side, it appears within \( A \).

Note that the function (5) derives from (3) by using an appropriate notation and setting \( \mu = 0 \). Thus, if we assume that \( \mu = 0 \), then the kernel based interpolant is defined by the linear system (3). In addition, since \( \Phi \) is a SPD kernel, the matrix \( A \) is positive definite, and so invertible.

### 3.2. Determination of the MPL criterion for kernel interpolation

While the discussion given in Subsection 3.1 would result in a two-dimensional optimization problem, here we use another technique known as **profile likelihood** in which we define \( \sigma^2 \) as a function of \( \varepsilon \), i.e., \( \sigma^2 = \sigma^2(\varepsilon) \).

Thus, our goal reduces to finding an optimal process variance \( \sigma^2_{\text{opt}} \) by maximizing \( p_{\Sigma, \varepsilon, Y}(\sigma^2|\Sigma = \sigma^2, \varepsilon = \varepsilon, Y = y) \propto p_{Y|\Sigma, \varepsilon}(y|\Sigma = \sigma^2, \varepsilon = \varepsilon), \) see [13].

The concept of maximizing the likelihood function requires the maximization of \( p_{Y|\Sigma, \varepsilon}(y|\Sigma = \sigma^2, \varepsilon = \varepsilon) \). However, the optimal value of \( \sigma^2 \) can be determined by minimizing the negative logarithm of (4) (multiplying by 2), i.e.,

\[
-2 \log \left( p_{Y|\Sigma, \varepsilon}(y|\Sigma = \sigma^2, \varepsilon = \varepsilon) \right) = N \log 2\pi + N \log \sigma^2 + \log \det A + \frac{1}{\sigma^2} y^T A^{-1} y.
\]

(7)
Differentiating (7) w.r.t. \( \sigma^2 \) and equating to zero, we obtain the optimal profile variance
\[
\sigma_{\text{opt}}^2 = \frac{1}{N} y^T A^{-1} y. \tag{8}
\]

Hence, by setting \( \mathbf{S} \) in (7), the minimization process that involves the profile likelihood gives
\[
-2 \log \left( p_{\mathbf{Y}|\Sigma, \mathcal{E}}(\mathbf{y}|\Sigma = \sigma_{\text{opt}}^2, \mathcal{E} = \varepsilon) \right) = N \log \left( y^T A^{-1} y \right) + \log \det A + N (1 + \log 2\pi - \log N).
\]

Now, ignoring the constant term \( N (1 + \log 2\pi - \log N) \), the cost function to minimize via the MPLE criterion is
\[
\text{MPLE}(\varepsilon) = N \log \left( y^T A^{-1} y \right) + \log \det A. \tag{9}
\]

**Remark 3.1.** The computation of the MPLE criterion \( \text{MPLE}(\varepsilon) \) for a range of \( \varepsilon \) values is carried out by applying the Cholesky factorization to the matrix, i.e., \( A = LL^T \). In practice, the use of such a factorization simplifies the determinant computation, because in this case \( \log(\det(A)) = \log(\det(LL^T)) = 2 \log(\det(L)) = 2 \sum_{i=1}^{N} \log(\sigma_i^2) \), where \( \sigma_i^2 \) denotes the eigenvalues of \( L \). Finally, in order to quickly find the optimal value of \( \varepsilon \), the minimum of the cost function \( \text{MPLE}(\varepsilon) \) can be determined by the MATLAB \texttt{fminbnd} function (or, in case, any other minimization routine).

4. Adaptive algorithm based on refinement and coarsening processes

In this section we describe our adaptive algorithm, which is based on a computational procedure. The latter enables us to refine and coarsen the distribution of interpolation points.

4.1. Residual sub-sampling procedure

First of all, we introduce a sequence of point sets \( X(0), X(1), \ldots \), such that \( X(k+1) \) is generated from \( X(k) = \{ x_i(k) \}_{i=1}^{N(k)} \) after applying some refinement and/or coarsening strategies. These updates depend on residual evaluations, which lead to an adaptive residual sub-sampling method. Therefore, the resulting process follows the common paradigm to solve, estimate and refine/coarsen till a criterion stop is satisfied.

Now, defining a check or test set \( T(k) = \{ t_i(k) \}_{i=1}^{N(k)} \subset \Omega \), for \( k \geq 0 \), we can evaluate the residual
\[
\xi(t_i(k)) = \left| s_{X(k)}(t_i(k)) - f(t_i(k)) \right|, \quad t_i(k) \in T(k), \tag{10}
\]
where \( s_{X(k)} \) is the interpolating function defined on the set \( X(k) \), \( N(k) \) being the number of points in \( T(k) \).

The residual error defined in (10) measures the deviation between the approximate solution and the function value at the point \( t_i(k) \). Thus, when \( t_i(k) \) lies in a smooth region, the absolute error \( \xi(t_i(k)) \) is expected to be small, whereas in the region of less regularity for \( f \), or around discontinuities, the residual error \( \xi(t_i(k)) \) is expected to be large. Notice that for \( k = 0 \) the check set \( T(0) \) is defined by starting from \( X(0) \), while for \( k \geq 1 \) the check set \( T(k) \) is dependent from \( X(k) \) and \( X(k-1) \).

Thus, the residual \( \xi(t_i(k)) \) in (10) is used as a criterion to define a refinement set \( X(k)_{\text{refine}} \) and a coarsening set \( X(k)_{\text{coarse}} \). In doing so, we need to introduce two tolerances (or thresholds) \( \theta_{\text{refine}} \) and \( \theta_{\text{coarse}} \), such that \( 0 < \theta_{\text{coarse}} < \theta_{\text{refine}} \). When the value of (10) is larger than \( \theta_{\text{refine}} \), we add the point \( t_i(k) \) in the refinement set \( X(k)_{\text{refine}} \), and so at next step the set \( X(k) \) needs to be replaced by \( X(k) \cup X(k)_{\text{refine}} \). Instead, whenever the error \( \xi(t_i(k)) \) is smaller than \( \theta_{\text{coarse}} \), we move a point from the active node set \( X(k) \) into the coarsening set \( X(k)_{\text{coarse}} \), and so \( X(k) \) is then updated with \( X(k) \setminus X(k)_{\text{coarse}} \). As a consequence, at \( (k + 1) \)-step of our adaptive process the set \( X(k) \) is updated by adding the refinement set \( X(k)_{\text{refine}} \) and deleting the coarsening set \( X(k)_{\text{coarse}} \), that is \( X(k+1) = \{ X(k) \cup X(k)_{\text{refine}} \} \setminus X(k)_{\text{coarse}} \). The iterative method concludes once the process of addition and/or removal was completed, returning the final set \( X(k^*) \), where \( k^* \) denotes the last iteration. A pseudo-code of this adaptive process is sketched in Algorithm 1.
Algorithm 1: Adaptive procedure

Step 1. Consider the set $X^0 \equiv X$ of interpolation points.

Step 2. Fix two positive tolerances (or thresholds) $\theta_{\text{refine}}$ and $\theta_{\text{coarse}}$ such that $0 < \theta_{\text{refine}} < \theta_{\text{coarse}}$.

Step 3. For $k = 0, 1, \ldots$ compute the $k$th approximate solution $s_{X^{(k)}}$.

Step 4. Define a set $T^{(k)}$ of test points.

Step 5. Evaluate the residual error $\xi(t_i^{(k)})$ in (10).

Step 6. If the error indicator

i) $\xi(t_i^{(k)}) > \theta_{\text{refine}}$, add the test point $t_i^{(k)}$ among the interpolation points

ii) $\xi(t_i^{(k)}) < \theta_{\text{coarse}}$, remove the interpolation node $x_i^{(k)}$ from $X^{(k)}$ and put it in the set $X_{\text{coarse}}^{(k)}$.

So define the sets

$$X_{\text{refine}}^{(k)} = \{ t_i^{(k)} \in T^{(k)} : \xi(t_i^{(k)}) > \theta_{\text{refine}}, i = 1, \ldots, N_{T^{(k)}} \}$$

$$X_{\text{coarse}}^{(k)} = \{ x_i^{(k)} \in X^{(k)} : \xi(t_i^{(k)}) < \theta_{\text{coarse}}, i = 1, \ldots, N_{T^{(k)}} \}$$

and construct the set

$$X^{(k+1)} = \left( X^{(k)} \cup X_{\text{refine}}^{(k)} \right) \setminus X_{\text{coarse}}^{(k)}$$

Step 7. Stop when $X_{\text{refine}}^{(k)} \cup X_{\text{coarse}}^{(k)} = \emptyset$.

Remark 4.1. This adaptive process is based on the computation of the residual (10). It is therefore evident that at each iteration the method requires to create an interpolant and to make some extra evaluations of the target function at the test points. This fact may not be a positive feature when the function evaluation is costly or possibly not available. However, in such a case one might use an alternative approach, which consists in generating for instance a local approximation around the test point, then considering the latter (instead of function value) in (10). Similar strategies have already been studied in e.g. [2, 22].

4.2. Connection between interpolation and check points

In this subsection we outline the strategy employed for the definition of the sets $X^{(k)}$ and $T^{(k)}$ above. Here we take $k$ fixed, meaning that $k$ is a generic iteration of our adaptive scheme.

In the sequel we describe the connection between the interpolation node set $X^{(k)}$ and the corresponding check point set $T^{(k)}$. By doing that, we focus more in detail on two specific situations that refer to one-dimensional and two-dimensional interpolation.

In 1D case, we start by generating a set $X^{(0)} = X$ of equally spaced points in the domain $\Omega = [a, b]$, $a, b \in \mathbb{R}$. Then, for $k \geq 0$, we define the set $T^{(k)}$ of test nodes that are the middle points taken from (sorted) interpolation nodes, i.e. $T^{(k)} = \{ t_i^{(k)} = 0.5(x_i^{(k)} + x_{i+1}^{(k)}), i = 1, \ldots, N^{(k)} - 1 \}$.

In 2D case, we follow the procedure described in [3, 22]. So we start from a set $X^{(0)} = X$ of equally spaced points in the square domain $\Omega = [a, b]^2$, $a, b \in \mathbb{R}$, and then we update the node set $X^{(k)}$ by applying the adaptive sub-sampling procedure. Now, for $k \geq 0$, we compute the halfway points of $T^{(k)}$ (red dots), as shown in Figure 1 where the blue points represent a portion of the set $X^{(k)}$ of interpolation nodes.
5. Numerical results and discussion

In this section we illustrate the effectiveness of our adaptive algorithms, which are implemented in MATLAB for kernel interpolation in one and two dimensions. All programs are run on a laptop with an Intel(R) Core(TM) i7-6500U CPU 2.50 GHz processor with 8GB RAM.

In the numerical experiments we test our interpolation scheme in order to analyze primarily the behavior of the algorithms in terms of both accuracy and computational efficiency. Then, we also emphasize on some important details for an adaptive method, that is, the number of iterations (# iter), the final number of points needed for achieving the algorithm convergence ($N_{fin}$) and the conditioning of the interpolation matrix ($\kappa(A)$). Furthermore, we compare our results with those of the adaptive algorithms in [9]. In our examples, in order to show how the new algorithms work, we consider various types of radial kernels thus involving both infinity and finite regularity RBFs like IMQ, M6, M4 and M2. In our MPLE-RSM we select the shape parameter $\varepsilon$ as discussed in Section 3. In particular, as suggested in Remark 3.1, the $\varepsilon$-choice via MPLE is determined by the use of MATLAB fminbnd minimization. Instead, as regards the comparison of our method with the RSM, we remind that the variable shape parameter selection concerning the RSM derives from the original paper [9].

In order to measure the accuracy of our adaptive method, we compute the $\infty$-norm error or maximum absolute error (MAE) given by

$$MAE = \|f - s_X\|_\infty = \max_{1 \leq i \leq N_e} |f(\xi_i) - s_X(\xi_i)|,$$

where the $\xi_i$ forms a suitable set of $N_e$ equally-spaced or gridded evaluation points. Further, by making use of the MATLAB cond command we provide an estimate of the condition number [4], while the efficiency of the adaptive algorithms is assessed by computing the execution (or CPU) time expressed in seconds.

5.1. Experiments for 1D adaptive interpolation

In this subsection we focus on one-dimensional interpolation. All these tests have been carried by starting from an initial point set $X^{(0)} \equiv X$, which consists of $N^{(0)} = 13$ equally-spaced points in the interval $[-1, 1]$. The threshold values are usually selected to be $\theta_{\text{refine}} = 10^{-5}, 10^{-6}$ and $\theta_{\text{coarse}} = 10^{-8}, 10^{-9}$. However, in our comparison between the residual sub-sampling algorithms, the refinement threshold $\theta_{\text{refine}}$ is often modified by keeping $\theta_{\text{coarse}}$ fixed.
In order to validate in depth our adaptive algorithms, we consider the following three benchmark target (or test) functions:

\[ f_1(x) = \frac{1}{1 + 25x^2}, \quad f_2(x) = \tanh(60x - 0.01), \quad f_3(x) = \frac{3}{8} \left[ \cos \left( (x + 1)^2 - 3 \right) \right]^4, \]

where \( f_1 \) is the well-known Runge function, \( f_2 \) represents the hyperbolic tan function, and \( f_3 \) denotes a univariate restriction of the so-called valley function (see [7, 9, 22]).

In Figure 2, we show some final point distributions obtained by adaptive interpolation. These results are three examples of possible application of MPLE-RSM, which considers different choices of kernel for \( f_1 \), \( f_2 \) and \( f_3 \). For the Runge function \( f_1 \) (top-left) we observe that the points cluster close to the boundaries where approximation turns out to be more challenging due to the one-side nature of the information, and at the origin in which the target function changes more rapidly. In case of hyperbolic tan function (top-right) we observe as the points distribute around the steepest part of \( f_2 \). A similar behavior also occurs for \( f_3 \), since the nodes tends to gather near the boundaries and the steepest areas of this function (bottom).

![Figure 2: Final point distribution using MPLE-RSM. 1D adaptive interpolation for \( f_1 \) with M4 (top-left), \( f_2 \) with IMQ (top-right) and \( f_3 \) with M6 (bottom). The chosen parameters are given in Tables 1, 2 and 3, respectively.](image-url)
This fact suggests that our method is working well. Moreover, the automatic selection of the optimal shape parameter also permits to control the condition number (in all cases < $10^{15}$, even for $C^\infty$ kernels), at the same time guaranteeing a high level of accuracy of the numerical method. Indeed, in the various situations, conditioning and CPU times assume quite similar values. It is, however, important to notice that the steep variation in the middle of $f_2$ leads to a remarkable increase in the final number of points, which the adaptive process needs to achieve the $\theta_{\text{refine}}$ threshold. In the latter case, in fact, for any choice of the kernel $N_{\text{fin}}$ assumes a value larger than 100, while for $f_1$ and $f_3$ the value of $N_{\text{fin}}$ is always smaller than 100.

| kernel | # iter | $N_{\text{fin}}$ | MAE   | $\kappa(A)$ | time |
|--------|--------|-----------------|-------|-------------|------|
| IMQ    | 4      | 51              | 2.1e-07 | 3.0e+12     | 0.6  |
| M6     | 10     | 50              | 6.7e-07 | 1.5e+11     | 0.8  |
| M4     | 12     | 54              | 8.9e-07 | 8.4e+09     | 1.1  |

Table 3: Results obtained by applying the MPLE-RSM with $\theta_{\text{refine}} = 10^{-5}$ and $\theta_{\text{coarse}} = 10^{-8}$ for $f_3$.

Finally, in Tables 4, 5 and 6 we compare our adaptive MPLE-RSM with the RSM proposed in [9]. Thus, we report the results obtained by varying the refinement threshold $\theta_{\text{refine}}$ for the M6 kernel. This analysis enables us to make some general observations. When the value of $\theta_{\text{refine}}$ is “small” the MPLE-RSM achieves convergence much faster than RSM. Furthermore, while for “large” values of $\theta_{\text{refine}}$ the number of points is pretty similar for the two methods, the MPLE-RSM usually needs much less points than RSM. These remarks are true for each of the target functions. However, from these experiments we can note that for the RSM [9] is not always possible to get any result, and so in the tables we denote this issue with the symbol –. Another drawback of the RSM is then due to severe difficulties in tuning the variable shape parameters. Unlike the MPLE-RSM, where the shape parameter choice is automatic for any radial kernel, the RSM
needs user’s action case-by-case thus making the $\varepsilon$-selections quite hard. This fact is particularly evident, either when the target function (and, as a consequence, the approximation problem) is quite complex, or the interpolation problem requires to be solved by kernels that have different degrees of smoothness.

5.2. Experiments for 2D adaptive interpolation

In this subsection we consider the two-dimensional adaptive interpolation algorithm. These experiments have been run by taking an initial point set $X^{(0)} \equiv X$, containing $N^{(0)} = 320$ uniformly distributed points on $[-1, 1]^2$. In order to test the node refinement process, as refinement thresholds we choose some
values of $\theta_{\text{refine}} \in [10^{-6}, 10^{-3}]$, while the coarsening tolerance is assumed to be fixed, i.e., $\theta_{\text{coarse}} = 10^{-8}$. Furthermore, as in the 1D case above, we compare the numerical results obtained by using the classical RSM in \cite{9} with the new MPLE-RSM. In doing that, we analyze the behavior of the two algorithms by varying the refinement threshold.

In our tests we analyze the performance of our algorithms taking the data values by three test functions. The former is known as a Franke-type function \cite{22}, and its analytic expression is

$$f_4(x,y) = \exp \left[ -0.1 \left( x^2 + y^2 \right) \right] + \exp \left[ -5 \left( (x - 0.5)^2 + (y - 0.5)^2 \right) \right] + \exp \left[ -15 ((x + 0.2)^2 + (y + 0.4)^2) \right] + \exp \left[ -9 \left( (x + 0.8)^2 + (y - 0.8)^2 \right) \right].$$

The latter is a hyperbolic tan function \cite{22} of the form

$$f_5(x,y) = -0.4 \tanh(20xy) + 0.6,$$

while the last one is an exponential function \cite{22} given by

$$f_6(x,y) = \exp \left[ -60 ((x - 0.35)^2 + (y - 0.25)^2) \right] + 0.2.$$

In Figure \ref{3} we give some graphical representations of the final point distribution, which are obtained by applying our adaptive MPLE-RSM algorithm. On the left, we report the graphs of the interpolating functions for $f_4$ (top), $f_5$ (center) and $f_6$ (bottom), also showing on the $xy$-plane at level $z = 0$ the final nodes deriving from the adaptive interpolation. On the right, instead, we explicitly show the 2D view of the point distributions. To give a generic idea about the flexibility of this kernel based interpolation approach, we depict the results with radial kernels of various regularity; as an example, in our work, we report the results attained in the following cases: M4 for $f_4$, IMQ for $f_5$ and M6 for $f_6$. More specifically, we can observe that for the Franke-type function $f_4$ the MPLE-RSM locates points in regions of rapid variation. The adaptive algorithm behaves in a similar way also when we consider the hyperbolic tan function $f_5$ and the exponential one $f_6$. In both cases the residual sub-sampling scheme puts more points in the domain where the functions change quickly or are picked.

In Tables \ref{7}, \ref{8} and \ref{9}, we illustrate the numerical results to see how the adaptive MPLE-RSM works when it is applied to solve some relevant approximation problems. As already shown in 1D interpolation above, in the tables we provide a detailed summary concerning the execution of the adaptive algorithm. In particular, we report the number of iterations needed to achieve convergence and the corresponding final number of points. Also in these 2D tests, we can observe that the MAE assumes values that are close – and however always lower – to the prefixed refinement threshold $\theta_{\text{refine}}$. Such data point out that the MPLE-RSM is able to make accurate predictions. In addition, we note that the near-optimal determination of the shape parameter via the MPLE technique enables us to control the kernel matrix conditioning. Indeed, in all reported results the condition number is smaller than $10^{10}$, even for $C^\infty$ RBFs like IMQ. As regards the CPU times we highlight that in this adaptive context the selected kernel can influence the execution time of the MPLE-RSM, which is subjected to an automatic addition or removal of points. Moreover, although the quality of results depends on the choice of the refinement threshold $\theta_{\text{refine}}$ and the complexity of the target function to be approximated, it is important to note as the number of refinement nodes remains relatively low. This fact is better explained in the following, where we compare the MPLE-RSM with the original RSM \cite{9}.

Therefore, in order to point out the benefit deriving from the use of the new adaptive algorithm, we conclude this numerical section by making a comparison between MPLE-RSM and RSM \cite{9}. In Tables \ref{10}, \ref{11} and \ref{12} we report the results obtained for various choices of the refinement parameter $\theta_{\text{refine}}$. In this study we also diversify the type of radial kernel and in particular, for the sake of brevity, we show the algorithm behavior by employing the IMQ for $f_4$, the M2 for $f_5$ and the M6 for $f_6$. From these tables, in which we report the final number of interpolation nodes required to meet both tolerances and the CPU times, it turns out to be undeniable the improvement provided by the novel adaptive MPLE-RSM. As a matter of fact, for any value of $\theta_{\text{refine}}$, the MPLE-RSM is much faster than the RSM. This good result in terms of computational efficiency is due to a better ability of our new approach in the selection of the shape...
Figure 3: Final point distribution using MPLE-RSM. 2D adaptive interpolation for $f_4$ with M4 (top), $f_5$ with IMQ (center) and $f_6$ with M6 (bottom). The chosen parameters are given in Tables 7, 8 and 9 respectively.

parameter via a MPLE based strategy. Consequently, the numerical method achieves convergence earlier and, at the same time, a smaller number of points is required. Furthermore, we can also note a growing enhancement in the performance of the MPLE-RSM (compared to the RSM), when the value of $\theta_{\text{refine}}$ becomes more demanding, i.e., the latter is assumed to be smaller and smaller. In some specific cases, then,
Table 7: Results obtained by applying the MPLE-RSM with $\theta_{\text{refine}} = 10^{-4}$ and $\theta_{\text{coarse}} = 10^{-8}$ for $f_4$.

| kernel | # iter | $N_{\text{fin}}$ | MAE   | $\kappa(A)$ | time |

Table 10: Comparison between RSM and MPLE-RSM obtained by using the IMQ kernel with $\theta_{\text{coarse}} = 10^{-8}$ for $f_4$.

Table 10: Comparison between RSM and MPLE-RSM obtained by using the IMQ kernel with $\theta_{\text{coarse}} = 10^{-8}$ for $f_4$.

it is even possible that the RSM does not converge (see the last row of Table 10). In conclusion, from these numerical experiments for 2D adaptive interpolation, we have once more put in evidence a concrete difficulty in the initialization of shape parameters for the RSM. From several tests it is evident how this (nonautomatic) choice can modify the performance of the algorithm, but the need of a preliminary user action makes the entire scheme highly unstable. However, to perform the comparisons discussed in this work, for the RSM we set as starting values of the shape parameter $\varepsilon = 3$ in Tables 10 and 11 and $\varepsilon = 4$ in Table 12.

6. Conclusions and future work

In this paper we solved two open problems in [9]. In fact, though the original method provides an effective adaptive scheme, it does not guarantee the invertibility of the interpolation matrix. This issue is essentially due to the variable shape parameter selection in the RSM, since the latter is characterized by a different choice of the shape parameter at every node. On the contrary, the new approach based on the MPLE criterion enables us on the one hand to make an optimal choice of the shape parameter associated with the kernel, and on the other one to guarantee existence and uniqueness of the RBF interpolation. Furthermore, the MPLE-RSM is thus automatically applicable to any kind of kernel, while the basic RSM needs a quite hard action of the user for the shape parameter selection.

As a future work we aim to improve the method proposed in this work, also for the solution of boundary value problems and partial differential equations.
