Quasi-molecular lines in Lyman wings of cool DA white dwarfs

Application to FUSE observations of G 231–40

Abstract. We present new theoretical calculations of the total line profiles of Lyman α and Lyman β which include perturbations by both neutral hydrogen and protons and all possible quasi-molecular states of H₂ and H₂⁺. They are used to improve theoretical modeling of synthetic spectra for cool DA white dwarfs. We compare them with FUSE observation of G 231–40. The appearance of the line wings between Lyman α and Lyman β is shown to be sensitive to the relative abundance of hydrogen ions and neutral atoms, and thereby to provide a temperature diagnostic for stellar atmospheres and laboratory plasmas.

Key words. line: profiles – radiation mechanisms: general – stars: atmospheres – stars: individual: G231-40 – white dwarfs – ultraviolet: stars

1. Introduction

Structures in the Lyman α and Lyman β line wings have been identified with free-free transitions which take place during binary close collisions of the radiating H atom and a perturbing atom or ion (Allard et al. 1998a, 1999b, 1999). The characteristics of these features (position, amplitude, and shape), due to the formation of quasi-molecules during collisions between the radiating atom and perturbers, depend directly on the potential energy curves correlated to the atomic levels of the transition (Allard & Kielkopf 1982).

Two satellite absorption features at 1058 Å and 1076 Å due to collisions of atomic hydrogen with protons were first identified in the spectrum of the DA white dwarf Wolf 1346, as observed with the Hopkins Ultraviolet Telescope (Koester et al. 1996). These satellites in the red wing of Lyman β are in the Far Ultraviolet Spectroscopic Explorer (FUSE) spectral range (Moos et al. 2000); furthermore, Lyman β profiles are also the subject of an ongoing study of the far ultraviolet spectrum of dense hydrogen plasmas.

In Allard et al. (1998a) we presented theoretical profiles of Lyman β perturbed solely by protons. The calculations were based on the accurate theoretical H₂⁺ molecular potentials of Madsen & Peek (1971) to describe the interaction between radiator and perturber, and dipole transition moments of Ramaker & Peek (1972). The line profiles were included as a source of opacity in model atmospheres for hot white dwarfs, and the predicted spectra compared well with the observed ORFEUS and FUSE spectra (Koester et al. 1998; Wolff et al. 2001).

Ab initio calculations of Drira (1999) of electronic transition moments for excited states of the H₂ molecule and molecular potentials of Detmer et al. (1998) allowed us to compute Lyman β profiles perturbed by neutral atomic hydrogen (Allard et al. 2000). The appearance of a broad satellite situated at 1150 Å makes necessary to take into account the total contribution of both the Lyman α and Lyman β wings of H perturbed simultaneously by neutrals and protons.

We show that the shape of the wings in the region between Lyman β and Lyman α is particularly sensitive to the relative abundance of the neutral and ion perturbers responsible for the broadening of the lines.

These new profiles have been used to predict synthetic spectra for cool DA white dwarfs which present structures at 1600 Å and 1400 Å in the Lyman α wing due respectively to quasi-molecular absorption of the H₂ and H₂⁺ molecules. These last two structures have been demonstrated to be a very sensitive temperature indicators in DA white dwarfs. The relative strength of these two satellite features depends very strongly on the degree of ionization in the stellar atmosphere, and thus on the stellar parameters T_eff and log y (Koester & Allard 1993; Koester et al. 1994; Bergeron et al. 1995).
2. Theoretical line profiles

2.1. Theory

We use a general unified theory in which the electric dipole moment varies during a collision; a detailed description of the theory applied to the shape of the Lyman lines has been given by Allard et al. (1999). The obtained line profiles fit the spectra of laser-produced hydrogen plasmas (Kielkopf & Allard 1998).

Our approach requires prior knowledge of accurate theoretical molecular potentials to describe the interaction between radiator and perturber, and knowledge of the variation of the radiative dipole moment with atom-atom and atom-ion separation for each molecular state. This effect is important when the dipole moment varies in the region of inter-nuclear distance where the satellite is formed, and thus cannot be neglected. In the case of Lyman \( \beta \) satellites, due to H–H\(^+\) collisions, we have shown that large changes (up to 60\%) in the intensity of the satellites may occur when the variation of the dipole moment is taken into account (Allard et al. 1998). This result is also valid for other lines; it increases by a factor of about 2 the main satellites of Lyman \( \alpha \) (Allard et al. 1999). Previous line profile calculations using constant dipole moment have been used to interpret IUE (International Ultraviolet Explorer) and Hubble Space Telescope spectra by Koester & Allard (1993), Koester et al. (1994), and Bergeron et al. (1995). The synthetic spectra presented here used improved Lyman \( \alpha \) line profiles of Allard et al. (1998) which have been already included in stellar atmosphere programs for the computation of stellar atmosphere model and synthetic spectra of \( \lambda \) Bootis stars. A comparison of these calculations with observations made with the IUE demonstrated that these last improvements are of fundamental importance for obtaining a better quantitative interpretation of the spectra and for determining stellar atmospheric parameters (Allard et al. 1998).

2.2. Lyman \( \beta \) in H–H collisions

The Lyman profiles and satellites are calculated at the low densities met in the atmospheres of stars. The typical particle densities (10\(^{15}\) to 10\(^{17}\) cm\(^{-3}\)) allows us to use an expansion of the autocorrelation function in powers of density as described in Allard et al. (1994) and Royer (1971). Line profiles are normalized so that over 1/\( \lambda = \omega \) (cm\(^{-1}\)) they integrate to 1.

The only line feature of the Lyman \( \beta \) profile is a broad absorption line situated at 1150 Å due to the \( B^+^\prime B \ 1\Sigma_{g}^+ \rightarrow \ X \ 1\Sigma_{g}^+ \) molecular transition of H\(_2\) (Fig. 1). The recent ab initio calculations of Spielfiedel (2001, private communication) have shown that for the isolated radiating atom (\( R \rightarrow \infty \)) this transition is not asymptotically forbidden as it was explicitly stated in Allard et al. (2000).

The line satellite shown in Fig. 1 presents a shoulder at 1120 Å, a similar shape has been obtained for the 1600 Å satellite. In Fig. 6 of Allard et al. (1999) both theory and experiment show an oscillatory structure between the satellite and the line, with a minimum at about 1525 Å. These oscillations are an interference effect (Royer 1971; Sando & Wormhoudt 1973), and are expected to depend on the relative velocity of the collision and therefore on temperature.

This satellite of Lyman \( \beta \) is quite far from the unperturbed Lyman \( \beta \) line center, actually closer to the Lyman \( \alpha \) line. It is therefore necessary to take into account the total contribution of both the Lyman \( \alpha \) and Lyman \( \beta \) wings of H perturbed simultaneously by neutrals and protons and to study the variation of this part of the Lyman series with the relative density of ionized and neutral atoms.

2.3. Lyman \( \beta \) in H–H and H–H\(^+\) collisions

In Allard et al. (1998a) we presented Lyman \( \beta \) profiles perturbed by protons. The line profile calculations were done without using the expansion in density and then were valid from the center to the far wing and allowed a comparison of the amplitudes of the satellites to the line core. The profiles at different densities of H\(^+\) were displayed in Fig. 8.

In Fig. 2 we show the sum of the profiles of Lyman \( \alpha \) and Lyman \( \beta \) perturbed by collisions with neutral hydrogen and protons for different densities \( n_H \).

We can see that a ratio of 5 between the neutral and proton density is enough to make the quasi-molecular H\(_2\) satellite appear in the far wing. Note that the 1120 Å shoulder of the satellite is still visible in the total profile.

3. Synthetic spectra for DA white dwarfs

We now take into account these absorption features of the H\(_2\) and H\(_2\) quasi-molecules to calculate synthetic spectra for DA white dwarfs. Atmosphere models and synthetic spectra have been calculated using the computer programs TLUSTY and SYNSPEC (Hubeny 1988; Hubeny & Lanz 1992, 1995). The LTE model atmospheres assume a pure hydrogen composition including the quasi-molecular opacities.

Below \( T_{\text{eff}} = 15000 \) K, the atmosphere of DA white dwarfs become convective, and model atmospheres for these stars are usually calculated using several variants of the standard mixing-length theory. According Bergeron et al. (1992), we used the so-called ML2 prescription with \( \alpha = 0.6 \), which

\[ n_H = 1 \times 10^{16} \text{ cm}^{-3}. \]
was shown to provide excellent internal consistency between ultraviolet and optical temperatures.

The temperature range where both H$_2$ and H$_2^+$ Lyman $\beta$ satellites are visible is relatively small; roughly between 14 500 to 11 000 K (Fig. 3, upper panel). This dependence of the theoretical profiles on temperature is extremely strong because of the relative importance of perturbations by neutral versus ionized hydrogen. The satellite appearance is then very sensitive to the degree of ionization and may be used as a temperature diagnostic.

In order to see all the Lyman line satellites, synthetic spectra are plotted from 1020 to 1800 Å (Fig. 3, lower panel). Below $T_{\text{eff}} = 13\,000$ K the H$_2^+$ starts to disappear but the broad H$_2$ satellite at 1150 Å is still present and the one at 1600 Å slowly increases.

4. $FUSE$ observations of G 231–40

4.1. Observations and data reduction

G 231–40 (WD 2117 + 539) is a cool DA white dwarf located at Galactic coordinates $l = 95.0^\circ$ and $b = -3.3^\circ$; it is a relatively bright white dwarf: $V = 12.3$. This target was observed with $FUSE$ as part of the French Guaranteed Time Observing Programs (program Q210). Two exposures were obtained on 2001 July 3 in time-tagged photon address mode (TTAG) with the object in the large aperture (LWRS). The total duration was ~1.6 h (see Table 1). Details of the $FUSE$ instrument may be found in Moos et al. (2000) and Sahnow et al. (2000).

The one-dimensional spectra were extracted from the two-dimensional detector images and calibrated using version 2.0.5 of the CaFUSE pipeline. The eight $FUSE$ detector segments of the two exposures (i.e. 16 spectra) were co-added and projected on a 0.16 Å-pixel base, i.e. pixels about 25 times larger than the original $FUSE$ detectors pixels. This degradation of the $FUSE$ spectral resolution (typically $\lambda/\Delta \lambda \approx 15\,000$ for this kind of target in the large slit; see Hébrard et al. 2002; Wood et al. 2002) is of no effect on the shapes of the large stellar features which we study and allows us to increase the signal-to-noise ratio. At this resolution, no spectral shifts were detected between the 16 different co-added spectra.

Poor quality edge of each segment were not included in the sum. We used the following spectral ranges for each segment: 1010−1085 Å (SiC1A), 910−992.5 Å (SiC1B), 922−1005 Å (SiC2A), 1016−1101 Å (SiC2B), 1004−1081.5 Å (LiF1A), 1096–1187 Å (LiF1B), 1087–1181 Å (LiF2A), and 1012−1073 Å (LiF2B). As the LiF1B segment presents a known large-scale distortion (“the worm”, D. Sahnow 2000, private communication) in the flux calibration around 1120–1170 Å (see, e.g., Hébrard et al. 2002), we normalized the large-scale shape of the LiF1B segment to the shape of the LiF2A segment, using a polynomial fit. We also did not include the part of the LiF2A spectra in the ranges 1134.6–1135.6 Å and 1151.5–1153 Å because they were deteriorated by the so-called “walk” problem, which is a distortion in the $FUSE$ spectra at airglow wavelengths ($\lambda$ 1134 Å N$\lambda$ and $\lambda$ 1152 Å O$_i$ lines in the present case) caused by variation of position with pulse height (Sahnow 2001, private communication). The final $FUSE$ spectrum is plotted in Fig. 4. Note that the interstellar N$\lambda$ 1134 Å triplet is detected on this line of sight.

Since 2001, repeated observations of standard white dwarfs indicate a slow degradation in the effective area of the $FUSE$ spectrograph. The decline affects the flux up to 20%, and that mainly for the LiF2A channel. A dome-dependent flux correction is in development for a future version of the pipeline, but is not included in the CaFUSE version 2.0.5.

In order to complement the 910−1187 Å $FUSE$ spectrum, we retrieved two $IUE$ low dispersion spectra of G 231–40 from the STScI MAST archive. These spectra were obtained in March 1983 and they were reduced using the NEWSIPS processing (see Table 1). They yield the spectral coverage 1150−1980 Å at a resolution of about 7 Å (Wegner 1984). The flux calibration of the $FUSE$ and the $IUE$ spectra are in good agreement (see Fig. 4, lower panel).

4.2. Comparison with theoretical spectra

As a change in temperature can be compensated by a change in surface gravity we have used log $g$ determined from optical analysis. Holberg et al. (1998) give (14 490; 7.85) for ($T_{\text{eff}}$; log $g$), the atmospheric parameters being determined from spectroscopic observations by Bergeron et al. (1992). Model atmospheres and synthetic spectra were calculated in the range 15 500 to 14 500 K by steps of 100 K, using log $g = 7.85$.

H$^+$ opacity (Wishart 1979) has been added in the atmosphere model calculation and gives a feature at 1130 Å also present in the $FUSE$ observation (see Fig. 4).

Figure 4, upper panel, shows the comparison of the $FUSE$ observation with our best fit obtained for $T_{\text{eff}} = 14\,800$ K. The decreasing of sensitivity on the segment LiF2A (Sect. 4.1) is the main explanation of the difference between the data and the model between 1120 and 1180 Å. The H$_2$ satellite (1150 Å) is no more visible, as expected, in this range of temperature.

Figure 4 shows a good agreement between the $FUSE$ and $IUE$ observations of Lyman lines and predicted spectra over the...
Fig. 3. Synthetic spectra for DA white dwarfs including Lyman $\alpha$ and Lyman $\beta$ satellites, on spectral ranges 1020–1200 Å (upper panel) and 1020–1800 Å (lower panel). $T_{\text{eff}} = 14\,500, 14\,000, 13\,500, 13\,000$ K (from top to bottom) and $\log g = 8.0$. The flux, at the stellar surface, is integrated over angles.

Fig. 4. $FUSE$ (1020–1187 Å, upper and lower panels) and $IUE$ (1150–1800 Å, lower panel) spectra of G 231–40 compared with a theoretical model for $T_{\text{eff}} = 14\,800$ K and $\log g = 7.85$. Emissions at Lyman $\alpha$, Lyman $\beta$, and 1027.5 Å are due to H$^{-}$ and O$^{-}$ airglow. The difference between the data and the model between 1120 and 1180 Å is mainly due to an uncorrected decreasing of sensitivity on the $FUSE$ segment LiF2A (see Sect. 4.1). Notice the H$^{-}$ feature at 1130 Å.
whole range from 1020 to 1800 Å using atmospheric parameters determined from the optical range.

The feature near 1995 Å due to a Lyman γ satellite, which is visible in the spectra of hotter objects, is no more present in the temperature range of G 231–40 (the flux of G 231–40 is below $1 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$ at 995 Å). It was visible in FUSE observations of CD –38°10980 (Wolff et al. 2001), HUT spectrum of Wolf 1346 (Koester et al. 1996), and in some ORFEUS spectra (Koester et al. 1998). It was also recently seen in FUSE spectra of Sirius B (Holberg et al. 2002). This feature, due to a Lyman γ satellite, is now included in our calculations. We have shown that a larger temperature is required to get it detectable (Allard et al. 2002).

### 5. Conclusion

From theoretical profiles including the new Lyman β opacities it can be predicted that Lyman β satellites should be detectable roughly between 25 000 K to 11 000 K. Within this range in a very small domain of temperatures, the whole profile should present H$_2$ and H$_2$* satellites of the Lyman α and Lyman β lines. FUSE observations of cooler white dwarfs in the ZZ Ceti range stars would offer the best opportunity to determine accurate stellar parameters as $T_{\text{eff}}$ and log g for these stars.

### Acknowledgements

This work is based on data obtained for the French Guaranteed Time by the NASA-CNES-CSA FUSE mission operated by the Johns Hopkins University. I.H. would like to thank the PNPS (Programme National de Physique Stellaire) for travel support to IAP where part of this work was done. We would like to thank Jean Dupuis for useful comments on this work.
