ABSTRACT

Nanoporous gold fabricated via anodization in a buffer solution comprising potassium chloride served as an effective scaffold for the direct electron transfer-type bioelectrocatalysis of bilirubin oxidase from Myrothecium verrucaria (BOD). BOD adsorbed on a porous gold electrode showed an increased population of effective orientations required for direct electron transfer reactions. The catalytic current of BOD reached an oxygen-transfer-limited value at the nanoporous gold electrodes despite neutral conditions.

1. Introduction

Direct electron transfer (DET)-type bioelectrocatalysis is a reaction, in which electrons can directly interact with enzymes and electrodes.1 Bilirubin oxidase (BOD) belongs to a family of multicopper oxidases, which catalyze the reduction of oxygen (O2) to water.2 Because BOD is reported to have high activity in DET-type catalytic reaction under neutral conditions,3 it is considered as a promising catalyst for biocathode in biosensors, biofuel cells, bioreactors, and biosupercapacitors.2 BOD receives four electrons at the T1 site.2 The DET-type catalytic activity can be improved by accelerating the electron transfer kinetics, which is achieved by shortening the distance between the T1 site of the enzyme and the electrode surface. An improved catalytic activity can also be achieved by increasing the amount of BOD adsorbed on the surface.

In this regard, porous electrodes with large surface areas are attractive scaffolds for the DET-type bioelectrocatalysis.4 Porous structures are convenient and essential for increasing the amount of immobilized BOD per projected area. Additionally, their curvature effect can facilitate the interfacial electron transfer kinetics.5 Porous gold materials are inert electrodes having controllable pore structures.6 In recent years, the fabrication of porous gold electrodes via the anodization of gold electrodes in solutions containing a reductant has been actively investigated, owing to the ease of this method.7 Although, the nanoporous gold prepared by the anodization in oxalic acid or glucose solutions serves as an effective scaffold for the DET-type bioelectrocatalysis of BOD, it also requires a long electrolysis time for fabrication.8,9 This study reveals that the anodization of gold electrodes in a chloride ion-containing solution can provide an effective scaffold for the DET-type bioelectrocatalysis of BOD in a short period. The orientation of BOD at the nanoporous gold electrode has been discussed based on the kinetics of the bioelectrocatalysis.

2. Experimental

BOD (EC 1.3.3.5), derived from Myrothecium verrucaria, was purchased from Amano Enzyme Inc. (Japan) and used without further purification. Au disk electrodes with a diameter of 3.0 mm were purchased from BAS Inc. (Japan). All the chemicals used in this study were of analytical grade and purchased from Wako Pure Chemical Ind. Ltd. (Japan). All the solutions were prepared with ultrapure water (>18.2 MΩ cm−1).

Electrochemical measurements were performed on an electrochemical analyzer (ALS 611B or 714C, BAS Inc., Japan). Steady-state voltammetric measurements were conducted with rotating disk electrodes (RRDE-2, BAS Inc., Japan) at a rotating speed of 4000 rpm. A platinum-deposited titanium mesh was used as the counter electrode. All the potentials in this study are in reference to an Ag|AgCl|sat.KCl electrode. All the measurements were obtained at 25.0 ± 0.2 °C using a water-jacketed cell.

BOD-immobilized nanoporous Au electrodes were prepared as follows (details are given in SI). The Au electrodes were polished with alumina slurry (1 µm and 0.05 µm successively) and then rinsed with water. The Au electrodes were anodized at 1.19 V in a buffer solution comprising potassium chloride served as an effective scaffold for the direct electron transfer-type bioelectrocatalysis of bilirubin oxidase from Myrothecium verrucaria (BOD). BOD adsorbed on a porous gold electrode showed an increased population of effective orientations required for direct electron transfer reactions. The catalytic current of BOD reached an oxygen-transfer-limited value at the nanoporous gold electrodes despite neutral conditions.
Similar to those reported previously, the pores seem to be sufficiently large to allow its penetration. The electrochemically active surface area of the electrode was evaluated based on the non-Faradaic current under anaerobic conditions. The ratio of the charging current of the anodized Au electrode to that of the planar electrode at 0.05 V ($r_t$) has been used as a measure of the roughness factor of the anodized Au electrodes.

Figure 2A shows the rotating disk cyclic voltammograms (RDCVs) recorded at the BOD-adsorbed nanoporous Au electrodes anodized for 20 s ($r_t = 6$). The solid and dotted lines indicate the voltammograms recorded at pH 7.0 under O$_2$-saturated and anaerobic conditions, respectively. Catalytic reduction of O$_2$ was observed at the BOD-adsorbed nanoporous Au electrode. A typical sigmoidal voltammogram has been reported for the electrode-enzymatic reaction-controlled bioelectrocatalysis of BOD (cf. planar Au electrodes). The half-wave potential was 0.45 V. This value agrees with the redox potential of the T1 site of BOD ($= 0.460$ V at pH 7.0). Therefore, it can be concluded that a direct communication with T1, and not T2/3 cluster of BOD is predominant at the nanoporous Au electrodes.

The dashed line in Fig. 2A shows the O$_2$-reduction at the unmodified nanoporous Au electrode. The direct O$_2$ reduction current at the nanoporous Au electrode was negligibly smaller than the catalytic reduction current of O$_2$ at the BOD-modified electrodes. The diffusion-limited current density under the RDCV conditions ($= 8.4$ mA cm$^{-2}$) implies that the steady-state current is mainly controlled by the electro-enzymatic reaction. The limiting catalytic reduction current density of the nanoporous Au electrode was found to be 300 times higher than that of the BOD-adsorbed planar Au electrode. The increase in the catalytic current density of the nanoporous Au electrode was greater than what was expected from the observed increase in the electrochemically active surface area. The result indicates that the DET-type bioelectrocatalysis of BOD is facilitated by an increase in not only the adsorbed amount of BOD, but also the population of the suitable orientation of adsorbed BOD.

The orientation of the adsorbed BOD was analyzed by the model of a randomly oriented spherical enzyme at a flat surface (details are shown in SI). There was no observable difference in the dispersion in the orientation of BOD ($\Delta d$) between the nanoporous and the planar Au electrodes. In contrast, assuming that the value of $k_e$ remains constant, the effective amount of BOD at the nanoporous Au electrode was evaluated to be 300 times larger than that at the planar Au electrode. The increase in the effective amount of BOD cannot be simply explained by an increase in the electrochemically active surface area. A possible explanation is that most of the adsorbed BOD molecules on the planar Au surface have inactive orientations for the DET-type bioelectrocatalysis. The population of the enzymes that can play the role of a good catalyst increased drastically at the nanoporous Au surface owing to the curvature effect. Further study is required for the direct quantification of the adsorbed BOD.

The electrochemically active surface area of the nanoporous Au electrode increased with the anodization time. The solid line in Fig. 2B shows the RDCVs of O$_2$ reduction on the nanoporous Au electrode prepared with an anodization time of 450 s ($r_t = 200$). In step with the growth of the surface area, the direct O$_2$-reduction activity of the nanoporous Au electrode increased significantly at potentials lower than 0.2 V (dashed line in Fig. 2B); however, the contribution of the DET-type bioelectrocatalytic O$_2$-reduction by BOD was still dominant. The DET-type O$_2$ reduction reached the limited steady-state at potential values more negative than 0.3 V with the current density being approximately $-5.5$ mA cm$^{-2}$. This value is almost identical with the limiting steady-state current density of the BOD-immobilized nanoporous Au electrode prepared by a 6 h anodization in 0.5 M glucose-containing phosphate buffer ($-5.1$ mA cm$^{-2}$) and is close to the mass transfer limited value ($-8.4$ mA cm$^{-2}$). Additionally, the anodization in KCl-containing solutions can be performed under quiescent conditions. Therefore, the present method for preparing nanoporous Au electrodes is
superior to those previously proposed\textsuperscript{8,9} in terms of time, energy, and operability.

4. Conclusions

The anodization of Au in KCl-containing buffer solutions under quiescent conditions was capable of producing effective scaffolds in a short time for the DET-type reaction of BOD. BOD immobilized on the nanoporous Au electrodes showed an increased population of the orientations favorable for the DET-type O\textsubscript{2} reduction compared with the planar Au electrode. The O\textsubscript{2} reduction current reached a value close to that limited by the O\textsubscript{2} mass-transfer at potentials lower than 0.3 V despite neutral conditions.
