The nature of charge stripe order and its relationship with structural phase transitions were studied using synchrotron X-ray diffraction in La$_{1.875}$Ba$_{0.125}$−$x$Sr$_x$CuO$_4$ (0.05 $\leq x \leq 0.10$). For $x = 0.05$, as temperature increased, incommensurate superlattice peaks associated with the charge order disappeared just at the structural phase transition temperature, $T_{d2}$. However, for $x = 0.075$ and 0.09, the superlattice peaks still existed as a short range correlation even above $T_{d2}$, indicating a precursor of charge ordering. Furthermore, temperature dependences of the superlattice peak intensity, correlation length, and incommensurability for $x = 0.05$ are different from those for $x = 0.075$ and 0.09. These results suggest that the transition process into the charge stripe order strongly correlates with the order of the structural phase transitions. A quantitative comparison of the structure factor associated with the charge order have been also made for all the samples.

I. INTRODUCTION

For the past several years, the relationship between charge stripe correlations and high-$T_c$ superconductivity has been intensively studied to clarify whether the role of the stripes for the superconductivity is positive or negative. Systematic studies on the La$_{1.6-x}$Nd$_x$CuO$_4$ (LNSCO) system have shown that for the Low-Temperature Tetragonal (LTT; $P4_2/nmc$) phase, incommensurate (IC) charge- and magnetic orders are stabilized and compete with superconductivity. This result provided a qualitative explanation for the long-standing mystery of the “1/8-problem” in La-214 cuprates, namely, the ordered state of charge stripes induced by the LTT transformation has a negative impact with high-$T_c$ superconductivity.

In the 1/8-hole-doped La$_{1.875}$Ba$_{0.125}$−$x$Sr$_x$CuO$_4$ (LBSCO) system, the crystal structure at the lowest temperature changes from LTT to a Low-Temperature-Orthorhombic (LTO; $Bmab$) phase via the Low-Temperature-Less-Orthorhombic (LTLO; $Pccn$) phase, as Sr-concentration $x$ increases (See Fig. 1). Fujita et al. have composed a detailed phase diagram of the crystal structure, IC charge/magnetic order, and $T_c$ for this system, where the charge order is stabilized only in LTT and LTLO phases (gray-hatched region in Fig. 1) and competes with superconductivity. On the contrary, the magnetic order in this system, which is robust in all the structural phases, shows a weak competition with the superconductivity.

The momentum structure and the temperature evolution of the charge order in the LBSCO system have been studied by Neutron diffraction as well as X-ray diffraction. In the LTT phase for $x = 0.05$, the IC modulation wave vector ($\equiv q_{ch}$) of the charge order is $(2\pi, 0, 1/2)$ with High-Temperature-Tetragonal (HTT; $I4/mmm$) notation. However in the LTLO phase for $x = 0.075$, $q_{ch}$ shifts away from the tetragonal-symmetric position to an orthorhombic-symmetric position, giving the wave vector of $(+2\pi, -2\pi, 1/2)$. The charge order in this system is stabilized just below the temperature where the structural phase transition from LTO into LTT or LTLO phase occurs (\(\equiv T_{d2}\)). Further, the ordered state evolves as the order parameter of the LTT or LTLO structure increases. These facts clearly show that a strong correlation exists between the charge order and the crystal structure, giving rise to suppression of superconductivity.

The charge order is detectable as lattice distortions in neutron and X-ray diffraction measurements. Recently, our preliminary X-ray diffraction measurements showed...
that the IC superlattice peaks at \((6 + 2\epsilon, 0, 11/2)\) are \(~10\) times stronger in intensity than that at \((2 + 2\epsilon, 0, 1/2)\). This is due to the amplitude of the scattering wave vector \(Q\) and the strong \(L\)-dependence of the structure factor for the superlattice peak, suggesting the importance of lattice distortions along the \(c\)-axis. This result indicates that the superlattice peak at higher-\(Q\) positions is much more sensitive to the charge order (or the lattice distortion) than that at lower-\(Q\) positions observed previously. This motivated us to conduct detailed measurements of IC superlattice peaks at higher-\(Q\) position, especially at \((6 + 2\epsilon, 0, 11/2)\) or \((6 - 2\epsilon, 0, 17/2)\), for \(La_{1.875}Ba_{0.125-x}Sr_xCuO_4\) using a synchrotron X-ray source for diffraction studies, which can elucidate detailed differences between the nature of charge stripes in the LTT and LTLO phases. In this paper, we show that for \(x = 0.075\) and \(x = 0.09\), short-range charge correlation starts appearing even above \(T_{d2}\) while the correlations appear just at \(T_{d2}\) for \(x = 0.05\). The results imply that the evolution of the charge stripes in the LTLO phase is different from that in the LTT phase, which relates to the order of the structural phase transition from the LTO to the LTT or LTLO phase. We also show the possibility that the displacement pattern of the atoms induced by the charge stripe order in the LTLO phase is different from that in the LTLO phase.

II. EXPERIMENTAL

Single crystals of LBSCO with \(x = 0.05, 0.075, 0.09,\) and \(0.10\) were cut into a cylindrical shape with dimensions of \(0.43\) mm diameter and \(5\) mm height, where the longest axis was parallel to the \(c\)-axis. X-ray diffraction experiments were performed at the Beam-line BL46XU and BL02B1 of Japan Synchrotron Radiation Research Institute in SPring-8. The X-ray energy was tuned to \(20\) keV and \(32.6\) keV using a Si(111) double monochromator at BL46XU and BL02B1, respectively. A double platinum mirror was inserted to eliminate higher order harmonics of the X-rays. The samples were cooled down to \(7\) K using a closed-cycled \(^4\)He refrigerator. In this paper, the reciprocal lattice is defined in the \(I4/mmm\) symmetry where the two short axes correspond to the distance between the nearest-neighbor Cu atoms along the in-plane Cu-O bond. Typical instrument resolutions along the \(H\)- and \(K\)-directions were 0.0039 \(\text{Å}^{-1}\) and 0.0037 \(\text{Å}^{-1}\) at \(Q = (6,0,6)\), and 0.0038 \(\text{Å}^{-1}\) and 0.0016 \(\text{Å}^{-1}\) at \(Q = (4,0,0)\), respectively. In the present study, we obtained nearly single-domain orthorhombic crystals for \(x = 0.075, 0.09,\) and \(0.10\). Note that the measurements for \(x = 0.05\) and \(0.075\) were done at BL46XU and those for \(x = 0.09\) and \(0.10\) were carried out at BL02B1.

As mentioned in Sec. II, we focused on the measurements of the superlattice peaks at \(Q_{ch} = (h \pm 2\epsilon, 0, l/2)\) with \(h = 6, 8\) and \(l = 11, 17\) in the present study, \((5, 0, 0)\) and \((7, 0, 0)\) Bragg reflections, which appears only in the LTT and LTLO phases and corresponds to the order parameter for these phases, were also measured to compare the phase transition of the charge order with that of the crystal structure. Note that we obtained a much better signal-to-noise ratio than that in the previous study by measuring the superlattice peaks at \(L = 11/2, 17/2\). Thus in this paper, we show \(q\)-profiles as a raw data, not as a subtracted data.

III. RESULTS

A. \(Q\)-dependence

\(Q\)-scan profiles along the \(K\)-direction of the superlattice peak and the \((5, 0, 0)\) peak for \(x = 0.05\), taken at \(T = 7\) K and \(40\) K, are shown in Fig. 2. The trajectory of the \(q\)-scan for the superlattice peak is shown in the inset of Fig. 2(a). \(H\)- and \(K\)-scans for the superlattice peak at \(T = 7\) K confirmed that a quartet of superlattice peaks are located exactly at \(Q_{ch} = (6 \pm 2\epsilon, 0, L/2), (6, \pm 2\epsilon, L/2)\) with \(2\epsilon = 0.2390(5)\) r.l.u., for which the geometry is consistent with the crystal symmetry of the LTT structure. The observed line-width along the \(K\)-direction for the superlattice peak is apparently broader than the instrument resolution (denoted in the figure as a bold horizontal line), giving a finite correlation length for the charge correlations. Note that the line-width along the \(H\)-direction for the superlattice peaks becomes also broader. As a result, the correlation lengths of the charge...
order along a- and b-axis (\(\xi_\text{ch}(a), \xi_\text{ch}(b)\)) are 98±4 Å and 110±4 Å at \(T = 7\) K, respectively. For the \((5,0,0)\) peak, the line-width along the \(K\)-direction is broader than the instrumental resolution while the line-width along \(H\)-direction reaches the resolution limit. Thus the correlation length for the LTTO structure, \(\xi_a\) and \(\xi_b\), are estimated to be > 300 Å and 196±5 Å, respectively, indicating a large anisotropy of the structural coherence or a mosaic spread due to a local disorder at the LTTO phase. At \(T = 40\) K, just below \(T_{d2}\), both the superlattice peak and the \((5,0,0)\) peak almost vanish, indicating that the charge order appears when the structural phase transition into the LTTO phase occurs.

Figures 3(a) and (b) show \(q\)-scan profiles along the \(K\)-direction of the superlattice peak and the \((5,0,0)\) peak for \(x = 0.075\), respectively, also taken at \(T = 7\) K and \(40\) K. The trajectory of the \(q\)-scan for the superlattice peak is displayed in the inset of Fig. 3(a). Since the single-domain-LTLO phase was obtained for the \(x = 0.075\) sample, we confirmed that a shift of the superlattice peaks from the highly symmetric axis clearly exists and the exact peak position is determined as \(Q_{\text{ch}} = (6 ± 2\xi, ±2\eta, L/2)\), \((6 ± 2\eta, ±2\xi, L/2)\) with \(2\xi = 0.3260(5)\) r.l.u. and \(2\eta = 0.0100(5)\) r.l.u. The observed line-width along the \(K\)-direction for the superlattice peak is much broader than the resolution, of which value is almost comparable to that for \(x = 0.05\). On the other hand, the line-width for the \((5,0,0)\) peak is resolution-limited, which is much sharper than that for \(x = 0.05\). Therefore, \(\xi_{\text{ch}}(a)\) and \(\xi_{\text{ch}}(b)\) for the charge order are 104±5 Å and 100±7 Å, respectively, while \(\xi_a\) and \(\xi_b\) for the LTLO structural coherence become long-ranged, which is in contrast with the results for \(x = 0.05\). At \(T = 40\) K, far above \(T_{d2}\), the broad superlattice peak clearly remains while the \((5,0,0)\) peak disappears, suggesting that the charge order exists even above \(T_{d2}\) with a short range correlation.

Figures 4(a) and (b) show \(q\)-scan profiles at \(T = 7\) K and \(40\) K along the \(K\)-direction of the superlattice peak through \((5.76, 0.01, 17/2)\) and the \((7,0,0)\) peak for \(x = 0.09\), respectively, taken at BL02B1. The trajectory of the \(q\)-scan for the superlattice peak is displayed in the inset of Fig. 4(a). This sample also had the single domain structure at LTLO phase. Thus the exact values of \(2\xi\) and \(2\eta\) are obtained as 0.2403(5) and 0.0103(3), respectively. As seen in Fig. 4(a), the line-width along \(K\)-direction is much broader than the resolution, which is also seen in the line width along \(H\). As a result, \(\xi_{\text{ch}}(a)\) and \(\xi_{\text{ch}}(b)\) for the charge order become 80±4 Å and 80±5 Å, respectively, which is shorter than those for \(x = 0.05\) and \(x = 0.075\). As for the \((7,0,0)\) peak, the line-width is somewhat broader than the resolution but \(\xi_a\) and \(\xi_b\) still extend over 200 Å. Although the \((5,0,0)\) peak completely disappears at \(T = 40\) K, the broad superlattice peak still clearly exists, which is consistent with the results of \(x = 0.075\). We had observed no superlattice peak in the \(x = 0.10\) sample but observed quite weak \((5,0,0)\) peak, indicating that the development of the order parameter for the LTLO phase is too small to stabilize the charge order.

In our previous paper, we argued for the anisotropy of \(\xi_{\text{ch}}(a)\) and \(\xi_{\text{ch}}(b)\), based on the comparison with the \(\xi_a\)
and $\xi_b$ of LTT/LTLO structure. However, the present study, under the fine resolution in $q$-space, has shown that the structural coherence for the LTT phase is apparently different from that for the LTLO phase, which was not observed in the previous experiment. Therefore in the present study, we evaluated the value of $\xi_{ch}(a)$ and $\xi_{ch}(b)$ by comparing the observed line-widths of fundamental Bragg peaks taken at room temperature, which corresponds to the accurate instrument resolutions.

### B. $T$-dependence

The temperature dependence of integrated intensity, line-width, $2\varepsilon$, and $2\eta$ were measured in detail for the IC superlattice peaks for $x = 0.05$, $x = 0.075$, and $x = 0.09$. For the $(5,0,0)$ and $(7,0,0)$ peak, the temperature dependence of integrated intensity and line-width were measured. All the measurements were performed during heating process. The results for $x = 0.05$ are summarized in Fig. 6. Figure 6(a) shows the temperature dependence of integrated intensity for the superlattice peak at $Q_{ch} = (6.239, 0.11/2)$ and the $(5,0,0)$ peak, where the intensities are normalized at 7 K. It is seen that the evolution of the intensity for the superlattice peak agrees well with that for the $(5,0,0)$ peak, apparently indicating that the charge order appears just at $T_{d2}$ ($\sim 40$ K) and the order parameters for the charge order and the LTT structure are strongly associated with each other. $\xi_{ch}(a)$ and $\xi_{ch}(b)$ for the charge order and $\xi_b$ for the LTT structure as a function of temperature are plotted in Fig. 6(b), for which values are obtained from the inverse of the intrinsic line-width. Note that $\xi_b$ for the LTT phase cannot be plotted in the figure because the correlation along the $a$-axis becomes almost a long-range one below $T_{d2}$. As temperature decreases, both $\xi_{ch}(a)$ and $\xi_{ch}(b)$ increase and show a nearly isotropic correlation with the length of $\sim 100$ Å. In the case of $\xi_{ch}(b)$, the temperature variation is quite similar to the development of $\xi_b$ for the LTT structure, implying that the growth of the charge correlation follows the evolution of the LTT structural coherence along the $b$-axis. As seen in Fig. 6(c), the incommensurability $2\varepsilon$ for $x = 0.05$ is nearly constant for all temperature regions below $T_{d2}$.

Figure 5 shows the summary of results for $x = 0.075$. The integrated intensity of the superlattice peak and the $(5,0,0)$ peak are depicted in Fig. 6(a) as a function of temperature. The $(5,0,0)$ peak starts growing below $T_{d2}$ ($\sim 34$ K) where the structural phase transition from the LTO to the LTLO phase occurs, while the superlattice peak appears at a much higher temperature than $T_{d2}$. In the lower temperature region, the temperature dependence of the superlattice peak intensity coincides with that for the $(5,0,0)$ peak intensity, which is also seen in the results for $x = 0.05$. However, above $T \sim 26$ K (indicated in Fig. 6 as a vertical dashed line), the superlattice peak intensity decreases more gradually than the decay of the $(5,0,0)$ peak with increasing temperature. The temperature dependence of the correlation length for the charge order is plotted in Fig. 6(b). Both $\xi_a$ and $\xi_b$ for LTLO structural coherence are not shown because the correlations along $a$- and $b$-axis reach at least 300 Å for all temperature regions below $T_{d2}$. At the lowest temperature, the correlation of the charge order is nearly isotropic with the length of $\sim 100$ Å which is almost identical to the charge correlation for $x = 0.05$. However, one can see in Fig. 6(b) that the correlation length suddenly changes around $T \sim 26$ K, which is not seen in the charge correlation for $x = 0.05$. As shown in Figs. 6(c) and (d), the incommensurability $2\varepsilon$ starts increasing with decreasing temperature and saturates below $\sim 26$ K while the peak shift $2\eta$ from the fundamental axis is almost temperature independent. These results imply that the charge order initially appears as short range correlations well above $T_{d2}$ and the correlation starts extending well below $T_{d2}$, where the IC modulation vector for the charge order is locked into $2\varepsilon = 0.236$ r.l.u.

The summary of the results for $x = 0.09$ is shown in Fig. 6. The temperature dependence of the integrated in-
FIG. 6: Temperature dependences of (a); integrated intensity for the superlattice peak (closed circles) and the (5, 0, 0) peak (open circles), (b); correlation length along the a-axis (closed circles) and b-axis (open squares), (c); $2\varepsilon$, (d); $2\eta$ for $x = 0.075$. Definitions of $2\varepsilon$ and $2\eta$ are shown in the inset of (c). The bold- and dashed curves are guides to the eye.

FIG. 7: Temperature dependences of (a); integrated intensity for the superlattice peak (closed circles) and the (7, 0, 0) peak (open circles), (b); correlation length along the a-axis (closed circles) and b-axis (open squares), (c); $2\varepsilon$, (d); $2\eta$ for $x = 0.09$. Definitions of $2\varepsilon$ and $2\eta$ are shown in the inset of (c). The bold- and dashed curves are guides to the eye.

tensity for the superlattice peak and the (7, 0, 0) peak are displayed in Fig. 6(a). The intensities are normalized by the values taken at $T = 7$ K. As temperature decreases, the structure phase transition into LTLO phase occurs at $T_{d2}$ ($\sim 30$ K) which follows the appearance of the superlattice peak. Around the lowest temperature, the temperature evolution of the superlattice peak is almost coincides with that of the (7, 0, 0) peak. However, above $T \sim 20$ K, denoted by the dashed line in the figure, the temperature dependence of the superlattice peak is considerably different from that of the (7, 0, 0) peak. As seen in Fig. 6(b), a characteristic change also occurs in the temperature dependence of $\xi_{ch}(a)$ and $\xi_{ch}(b)$, where the correlation length suddenly extends. Furthermore, the incommensurability $2\varepsilon$ saturates into 0.24 below 20 K (See Fig. 6(c)). These behaviors show that there is a characteristic temperature $T_{lock}$ also in $x = 0.09$, which is lower than that in $x = 0.075$. At the lowest temperature, $\xi_{ch}$ becomes almost isotropic but the correlation length remain $\sim 80$ Å, which is shorter than that in both $x = 0.05$ and $x = 0.075$. The result implies that the order parameter of the charge order for $x = 0.09$ is reduced comparing with that for $x = 0.05$ and $x = 0.075$. As shown in Fig. 6(d), $2\eta$ is also temperature independent.
This shift from the symmetry axis is quantified by the anisotropy of the second nearest-neighbor transfer integral due to the orthorhombic symmetry in the CuO$_2$ plane. However, a detailed displacement pattern of oxygen atoms associated with the charge order should be resolved to explain the origin of the peak shift.

IV. DISCUSSION AND CONCLUSIONS

A. Modulation wave vector of a charge order

We first refer to the IC modulation wave vectors of the charge order. The present study confirmed that the modulation vector $q_{ch}$ for $x = 0.05$, $x = 0.075$, and $x = 0.09$ is (0.239, 0.1/2), (0.236, -0.010, 1/2), and (0.240, -0.010, 1/2), respectively. Note that the concentration of (Ba + Sr) ions for the $x = 0.075$ sample is roughly estimated to be 0.117 by ICP emission spectroscopy, which is nearly consistent with the (0.118) for $x = 0.075$. Therefore, the effective concentration of doped-holes almost coincides with the incommensurability of the modulation wave vector, which suggests a 1/4-filling configuration in the charge stripes.

$q_{ch}$ for $x = 0.075$ and $x = 0.09$ shows that the IC modulation wave vector does not lie on the fundamental reciprocal axis (i.e. H, or K-axis), which has been originally found in the IC magnetic order of La$_2$CuO$_4$. This shift from the symmetry axis is quantified by the angle of $\theta_Y$ between the modulation wave vector and the $H$ (or K)-axis. The definition of $\theta_Y$ is displayed in Fig. 8(a). Fujita et al. have found that the amplitude of $\theta_Y$ in the LBSCO system is proportional to the square value of the orthorhombic distortion ($\equiv \theta_{ortho}$), which is quantified as the deviation from 90$^\circ$ in the angle between $H$- and $K$-axis in the HTT unit (See Fig. 8(a)). As shown in Fig. 8(b), $\theta_Y$ as a function of $\theta_{ortho}$ obtained by Fujita et al. (closed circles) agrees well with the results obtained in the present study (open squares). Note that $\theta_Y$ and $\theta_{ortho}$ for $x = 0.075$ and $x = 0.09$ are almost coincide within the experimental error. Theoretical work based on fermiology has pointed out that $\theta_Y$ can be understood as an anisotropy of the second nearest-neighbor transfer integral due to the orthorhombic symmetry in the CuO$_2$ plane. However, a detailed displacement pattern of oxygen atoms associated with the charge order should be resolved to explain the origin of the peak shift.

B. Order parameter of structural phase transitions and a charge order

Structural phase transitions from the LTO to LTLO, and from the LTO to LTT phase, in La-214 cuprates can be understood in terms of the Landau-Ginzburg free energy of the order parameter, which is described by the amplitude of the tilting of CuO$_4$ octahedra. In this framework, the LTO-LTT transition shows a first-order phase transition while the LTO-LTLO transition should be a second-order phase transition, which depends on the sign of the eighth-order term in expanding the Landau free energy. Therefore, the structural phase transition in $x = 0.05$ is a first-order while $x = 0.075$ and $x = 0.09$ should show a second-order phase transition. X-ray powder diffraction analyses have shown that the LTO-LTT transition in La$_{1.875}$Ba$_{0.125}$CuO$_4$ is a first order transition, where both the LTO and LTT phases coexist and the volume fraction of the LTT phase increases with decreasing temperature. Therefore, the temperature dependence of (5, 0, 0) intensity and $\xi_\parallel$ for $x = 0.05$, shown in Fig. 8(a) and (b), can be regarded as the change of the volume fraction of LTO and LTT structure. Based on this argument, it is plausible that the difference between the temperature evolution near $T_{d2}$ of the charge order for $x = 0.05$ and that for $x = 0.075$ and $x = 0.09$ closely correlates with the order of each structural phase transition: In the case of $x = 0.05$, there is no critical phenomenon associated with the charge order because the structural phase transition is a first order one. On the contrary, for $x = 0.075$ and $x = 0.09$, the short-range charge correlation above $T_{d2}$ is induced by the successive increase in structural instabilities or fluctuations near the second-order LTO-LTLO phase transition. It should be noted that X-ray diffraction integrates over both elastic and inelastic scattering. Therefore there is also a possibility that the weak signals above $T_{d2}$ indicate dynamical charge (stripe) correlations.

C. Correlation length

The coherence of the LTT structure for $x = 0.05$ along the b-axis ($\xi_\parallel$) extends with decreasing temperature but remains within a finite length ($\sim$ 200 Å). In contrast, the coherence of the LTLO structure for $x = 0.075$ and
$x = 0.09$ is almost long-ranged. The correlation length of the charge order, however, is less than $\sim 100$ Å for all the samples, which is much shorter than the structural coherence. These results show that the charge stripes in this system are essentially glassy or topologically disturbed. Comparing $\xi_{\text{ch}}$ with the correlation length of the magnetic order ($\equiv \xi_{\text{spin}}$) obtained by the previous neutron scattering study, we thus obtain the ratio: $\xi_{\text{spin}}/\xi_{\text{ch}} > 2$. Note that in LNSCO and La$_{5/3}$Sr$_{1/3}$NiO$_4$, $\xi_{\text{spin}}/\xi_{\text{ch}}$ is about $4$ and $3$, respectively. Zachar et al. have argued, from a theoretical standpoint, that in the case of $1 < \xi_{\text{spin}}/\xi_{\text{ch}} \lesssim 4$, charge stripes are disordered by non-topological elastic deformations, resulting in a Bragg-glass-like state or a discommensuration.

Charge correlation $\xi_{\text{ch}}$ for $x = 0.075$ and $x = 0.09$ becomes longer below around $T_{\text{lock}}$ where the evolution of the superlattice peak is superposed with that of $(5, 0, 0)/(7, 0, 0)$ peaks and the IC modulation wave vector is locked. Based on the stripe model, $\xi_{\text{ch}}(a)$ denotes the deformation of the periodicity or the discommensuration for charge stripes and $\xi_{\text{ch}}(b)$ corresponds to the mosaicity of stripes. From this point of view, the results for $x = 0.075$ and $x = 0.09$ indicate that the deformation of the stripe-periodicity and the stripe-mosaicity are reduced as temperature decreases and $2\xi$ is pinned finally at the value of hole concentration. If the 1/4-filling is robust in the charge stripes, the temperature variation of $2\xi$ indicates that the number of localized holes increases with decreasing temperature, which immobilizes charge stripes. The locking of the incommensurability is also seen in LNSCO and striped nickelates. However, the connection between the locking effect and the structural phase transition was not observed in either case. Note that the temperature dependence of the incommensurability for magnetic order should be compared with that of $2\xi$ in the $x = 0.075$ and $x = 0.09$ samples to clarify the microscopic interrelation between the spin- and charge correlations.

### D. Comparison of structure factors

We finally compare quantitatively the structure factors of the lattice distortion associated with the charge order for $0.05 \leq x \leq 0.10$. The integrated intensity of the superlattice peaks were converted into the absolute value of the structure factor $|F_{\text{obs}}|$ using the scale factor obtained from the measurements of fundamental Bragg intensities. The absolute value of the structure factor for the LTT/LTLO structure ($\equiv |F_{\text{obs}}|$) were also obtained to compare with each $|F_{\text{obs}}|$.

![FIG. 9: Absolute value of structure factor at $\sim 10$ K. for (a); $|F_{\text{obs}}|$ taken at four reciprocal lattice points as a function of Sr concentration. The results of Ba-free $x = 0.12$ (LSCO) are also shown in the figure.](image)

The results of Ba-free $x = 0.12$ (LSCO) are also shown in the figure. It shows that the absolute value of the structure factor $|F_{\text{obs}}|$ increases with Sr concentration in the LTLO phase. Thus we speculate that the charge order in the LTLO phase becomes more stable as a pinning potential in the CuO$_2$ plane increases, which is consistent with the fact that $T_{\text{lock}}$ becomes higher as Sr concentration increases. However, $|F_{\text{obs}}|$ of $x = 0.05$ in the LTLO phase is comparable with that of $x = 0.075$ in the LTLO phase while $|F_{\text{obs}}|$ of $x = 0.05$ is much stronger than that of $x = 0.075$. The result implies that the structure factor of the lattice distortion associated with the charge order in the LTT structure is different from that in the LTLO phase; namely, the displacement pattern of oxygen atoms in the LTT phase is different from that in the LTLO phase.

### E. Conclusions

The relationship between charge stripes and structural phase transitions was systematically studied for La$_{1.875}$Ba$_{0.125}$Sr$_x$CuO$_4$ with $0.05 \leq x \leq 0.10$. We have found that the short range charge correlations appear above $T_{d2}$ for $x = 0.075$ and $x = 0.09$ while the correlations starts growing just at $T_{d2}$ for $x = 0.05$. Furthermore in both the $x = 0.075$ and $x = 0.09$ samples, the temperature dependence of the correlation length and the incommensurability are different from those for the $x = 0.05$ sample. These facts are closely related with the order of the structural phase transitions from the LTO
phase to the LTLO or LTT phases. The quantitative comparison of the structure factors for the charge order and the LTT/LTLO structure reveals that the charge order becomes more robust as the order parameter of the LTLO structure increases. Comparison of $|F_{\text{obs}}|_{\text{ch}}$ for tetragonal $x = 0.05$ with that for orthorhombic $x = 0.075$ indicates that the displacement pattern induced by the charge order in the LTT phase is different from that in the LTLO phase. A detailed structure analysis in the charge ordered phase is required to discuss more quantitatively. The structure analysis for $x = 0.05$ is now in progress. Thus the detailed displacement pattern induced by the charge order will be clarified in the near future.

Acknowledgments

We thank M. Ito, K. Machida, H. Yamase, and O. Zacher for valuable discussions. This work was supported in part by a Grant-In-Aid for Young Scientists B (13740216 and 15740194), Scientific research B (14340105), Scientific Research on Priority Areas (12046239), and Creative Scientific Research (13NP0201) from the Japanese Ministry of Education, Science, Sports and Culture, and by the Core Research for Evolutional Science and Technology (CREST) from the Japan Science and Technology Corporation. The synchrotron X-ray experiments were carried out at the SPring-8 facility (Proposal No. 2002A0314, R03A46XU, 2003B0117, and 2004A2117).

13 The $q_{\text{ch}}$ for $x = 0.075$ has been obtained as $0.24 - 0.007 1/2$ at the previous experiment. However, the result of the present study is more reliable because the instrument resolutions and the statistics are much more improved than those of the previous work.
