I. INTRODUCTION

Most liquids contract upon cooling. This is not the case of water, a liquid where the specific volume at ambient pressure starts to increase when cooled below \( T = 4 \text{ °C} \).\(^{1,2}\) Besides, in a certain range of pressures, water also exhibits an anomalous increase in compressibility and specific heat upon cooling.\(^{3–5}\) Experiments, for Te,\(^{6}\) Ga, Bi,\(^{7}\) S,\(^{8,9}\) and Ge\(_{15}\)Te\(_{85}\),\(^{10}\) and simulations, for silica,\(^{11–14}\) silicon,\(^{15}\) and BeF\(_2\),\(^{11}\) show the same density anomaly.

Water also has dynamic anomalies. Experiments show that the diffusion constant, \( D \), increases on compression at low temperature, \( T \), up to a maximum \( D_{\text{max}}(T) \) at \( p = p_{D_{\text{max}}}(T) \). The behavior of normal liquids, with \( D \) decreasing on compression, is restored in water only at high \( p \), e.g., for \( p > p_{D_{\text{max}}}(T) = 1.1 \text{ kbar at 10 °C} \).\(^{2,3}\) Numerical simulations for SPC/E water\(^{21}\) recover the experimental results and show that the anomalous behavior of \( D \) extends to the metastable liquid phase of water at negative pressure, a region that is difficult to access for experiments.\(^{17–20}\) In this region the diffusivity \( D \) decreases for decreasing \( p \) until it reaches a minimum value \( D_{\text{min}}(T) \) at some pressure \( p_{D_{\text{min}}}(T) \) and the normal behavior, with \( D \) increasing for decreasing \( p \), is re-established only for \( p < p_{D_{\text{min}}}(T) \).\(^{17–19,21}\) Besides water, silica\(^{11,22}\) and silicon\(^{11}\) also exhibit a diffusion anomalous region.

It was proposed a few years ago that these anomalies are related to a second critical point between two liquid phases, a low density liquid and a high density liquid.\(^{24}\) This critical point was discovered by computer simulations. This work suggests that this critical point is located at the supercooled region beyond the line of homogeneous nucleation and thus cannot be experimentally measured. Even with this limitation, this hypothesis has been supported by indirect experimental results.\(^{25,26}\)

In order to describe the anomalies present in water and in other liquids, isotropic models have been used as the simplest framework to understand the physics of the liquid-liquid phase transition and liquid state anomalies. From the desire of constructing a simple two-body isotropic potential capable of describing the complicated behavior present in waterlike molecules, a number of models in which single component systems of particles interact via core-softened potentials\(^{27}\) has been proposed. They possess a repulsive core that exhibits a region of softening where the slope changes dramatically. This region can be a shoulder or a ramp.\(^{28–49}\) These models exhibit density, diffusion, and structural anomalies, but depending on the specific shape of the potential, the anomalies might be hidden in the metastable and unstable phases.\(^{49}\) The relation between the specific shape of the core-softened potential and the presence or not of the anomalies is still missing.

How does the specific shape of a core-softened potential affect the location of the anomalies and the critical points? In order to answer to this question in this paper we analyze a family of continuous core-softened potentials that exhibit two length scales, a shoulder followed by an attractive well. When the shoulder is purely repulsive, this core-softened potential represents the effective pair interaction between two neighbors tetramers\(^{44,50}\) and the density, the diffusion, and the structural anomalies are present.\(^{44,45}\) If the shoulder has a deep well with attractive forces, this potential is related to the effective interaction potential between two water molecules obtained from the ST4 (Ref. 51) or TIP5P (Ref. 52) models for water. In this case the effective potential is derived from the oxygen-oxygen radial distributions function, solving the Ornstein-Zernike equation by using an integral equation method.\(^{51,52}\) The resulting potential has a shoulder with a deep well at closest distance and a second well with lower energy at furthest distance. The detailed depth of the softening region depends on the approximations employed. This potential leads, as we are going see in this paper, to systems in which the anomalies are in the unstable region of the phase diagram while in the full ST4 and TIP5P systems the anomalies can be observed. It is important, therefore, to...
understand what is lost when one goes from the specific anisotropic ST4 and TIP5P potentials to the isotropic spherical symmetric case.

So, in this paper we study what happens with the region in the pressure-temperature phase diagram where the anomalies are located as the potential changes from a repulsive shoulder to a very deep well. Our results will shed some light not only in the use of spherical symmetric approximations of asymmetric potentials but will also help in designing potentials for new systems with anomalies.

The paper is organized as follows. In Sec. II the family of potentials is introduced and its link with the derivation of the integral equations is presented. In Sec. III these potentials are tested for presence density, diffusion, and structural anomalies and for the existence of two liquid phases and a critical points by molecular dynamic simulations. Conclusions are presented in Sec. IV.

II. THE MODEL

We study a system of \( N \) particles, with diameter \( \sigma \), where the pair interaction is described by a family of continuous potentials given by

\[
U(r) = \epsilon \left[ \left( \frac{\sigma}{r} \right)^a - \left( \frac{\sigma}{r} \right)^b \right] + \sum_{j=1}^{4} h_j \exp \left[ - \frac{(r - c_j)^2}{w_j^2} \right]. \tag{1}
\]

The first term is a Lennard-Jones potential-like and the second one is composed by four Gaussians, each one centered in \( c_j \). This potential can represent a whole family of intermolecular interactions, depending of the choice of the parameters \( a, b, \sigma, \{h_j, c_j, w_j\} \), with \( j = 1, \ldots, 4 \). The parameters are chosen in order to obtain a length scale potential.

In order to make the simulations in dimensionless units, the potential and the distances are given in dimensionless units, \( U^* = U/\gamma \) and \( r^* = r/r_0 \), where \( \gamma \) is the energy scale and \( r_0 \) is the length scale chosen so the closest approach between particles is about \( r^* = 1 \). All the parameters of the model are used in the simulations in units of \( \gamma \) and \( r_0 \). In this work \( \epsilon/\gamma = 0.02 \) and \( \sigma/r_0 = 1.47 \). Modifying \( h_1 \) in Eq. (1) allows us to change the depth of the hard-core well, as illustrated in Fig. 1. Here we use four different values for \( h_1 \) and they are expressed as a multiple of a reference value \( h_1^{\text{ref}} \) as shown in the Table I. For all the cases the values of \( a, b, \{c_j, w_j\} \) with \( j = 1, \ldots, 4 \) and \( h_1^{\text{ref}} \). Table II gives the parameter values in angstroms and kcal/mol consistent with modeling ST4 water. The depth of the region of softening of the potentials illustrated in Fig. 1 where chosen so that potential B is the shallow shoulder-like potential similar to the one studied by de Oliveira et al., which exhibits the anomalies, while for the potential D the region of softening has the same depth as the potential obtained by using the oxygen-oxygen radial distribution function for the ST4 model. In this case, the shoulder region has attractive forces. For comparison we also analyzed two other cases: Potential A with a ramplike shoulder and potential C with a very shallow shoulder.

The properties of the system were obtained by NVT molecular dynamics using Nose–Hoover heat-bath with coupling parameter \( Q = 2 \). The system is characterized by 500 particles in a cubic box with periodic boundary conditions, interacting with the intermolecular potential described above. All physical quantities are expressed in reduced units and defined as

\[
t^* = \frac{t m/\gamma}{r_0},
\]

\[
T^* = \frac{k_B T}{\gamma}.
\]
III. RESULTS

A. Pressure-temperature phase diagram

First, we are going to show the effects of the shoulder depth in the presence or not of the thermodynamic anomalies and the location in the pressure-temperature phase diagram of the different phases. Figure 2 illustrates the pressure-temperature phase diagram of the four cases. The system at high temperatures has a fluid phase and a gas phase (not shown). These two phases coexist at a first order line that ends at a critical point (see Table III for the pressure and the temperature values). At low temperatures and high pressures there are two liquid phases coexisting at a first order line (not shown) ending at a second critical point (see Table IV and Fig. 3 for the pressure and the temperature values) that is identified in the graph by the region where isochores cross.

In Fig. 2 at low temperatures and low pressures the dotted line separates the fluid phase from the amorphous region. The amorphous region is identified by the diffusion coefficient that becomes zero. For potential A, the amorphous region is located in a pressure range $-0.91 \leq p^* \leq 3.40$, for the B case this region is located in the range $-0.89 \leq p^* \leq 1.80$, and for the C case it is located in the range $-1.00 \leq p^* \leq 0.48$. The potential D does not have a stable amorphous phase. Hence, as the shoulder becomes deeper, the amorphous phase shrinks and moves to a lower pressure range.

At low temperatures and high pressures two liquid phases are present. As the shoulder becomes deeper the liquid-liquid coexistence line slides down to lower pressures and it goes to higher temperatures. This indicates that the deeper the shoulder the liquid-liquid phase transition stays stable for higher temperatures. Therefore, even though this

TABLE IV. Second critical point location for potentials A, B, C, and D.

| Potential | $T_{c2}^*$ | $p_{c2}^*$ |
|-----------|------------|------------|
| A         | 0.35       | 3.44       |
| B         | 0.48       | 1.86       |
| C         | 0.57       | 0.49       |
| D         | 0.81       | -0.33      |

FIG. 3. Location of the critical points on pressure-temperature phase diagram for cases A, B, C, and D.
transition only exists if the attractive part of the potential is present (the second length scale), the stability of the liquid phases is determined by the depth of the shoulder (the first length scale).

### B. Thermodynamics anomaly

The Fig. 2 also shows the isochores $0.30 \leq \rho^* \leq 0.65$ represented by thin solid lines. The temperature of maximum density (TMD) at constant pressure coincides with the minimum pressure on isochores, $(\partial p/\partial T)_p=0$. From the equation

$$\left(\frac{\partial V}{\partial T}\right)_p = -\left(\frac{\partial p}{\partial T}\right)_V \left(\frac{\partial V}{\partial p}\right)_T ,$$

(2)

it is possible to see that, for a fixed density, a minimum in the pressure as a function of temperature represents a maximum in the density as a function of temperature, named TMD given by $(\partial V/\partial T)_p=0$. The TMD is the boundary of the region of thermodynamic anomaly, where a decrease in the temperature at constant pressure implies an anomalous increase in the density and therefore an anomalous behavior of density (similar to what happens in water). Figure 2 shows the TMD as a solid thick line. For potentials A, B, and C, the TMD is present but for potential D no TMD is observed.

Similar to what happens with the location of amorphous region and of the second critical, as the shoulder becomes deeper, the region in the pressure-temperature phase diagram delimited by the TMD goes to lower pressures, shrinks, and disappears for case D, the potential with the deepest shoulder. As the region delimited by the TMD shrinks, it also goes to lower temperatures. For potential C the TMD line is located at temperatures below the temperature of the liquid-liquid critical point. The thermodynamic parameters that limits the TMD in phase diagram are shown in the Table V, where $p_l$ represents the values of $(\rho^*, T^*, p^*)$ for the point of the lowest pressure in the TMD line, $p_m$ is the point with the highest temperature, and $p_h$ is the point with the highest pressure.

The link between the depth of the shoulder and the presence or not of the TMD goes as follows. The TMD is related to the presence of large regions in the system in which

| Cases | $p_l$ | $p_m$ | $p_h$ |
|-------|-------|-------|-------|
| A     | 0.47  | 0.52  | 0.57  |
|       | 0.71  | 0.85  | 0.73  |
|       | 1.50  | 2.50  | 3.30  |
| B     | 0.46  | 0.50  | 0.54  |
|       | 0.67  | 0.76  | 0.63  |
|       | 0.90  | 1.40  | 1.80  |
| C     | 0.40  | 0.42  | 0.43  |
|       | 0.44  | 0.54  | 0.52  |
|       | 0.15  | 0.29  | 0.36  |
particles are in two preferential distances represented by the first scale and the second scale in our potential. For normal liquids, as the temperature is increased, the percentage of particles at closest scales decreases (see case D in the Fig. 4), for the anomalous liquid (see cases A, B and C in the Fig. 4) there is a region in the pressure-temperature phase diagram where as the temperature is increased the percentage of particles at the closest distance increases. This increase in the percentage is only possible if particles move from the second to the first scale. In the first case, the decrease in particles in the first scale leads to a decrease in density with the increase in temperature, behavior expected for normal liquids. In the second case, the increase in particles in the first scale leads to an increase in density with temperature that characterizes the anomalous region. The anomaly is, therefore, related to the increase in the probability of particles to be in the first scale when the temperature is increased while the percentage of particles in the second scale decreases.

C. Diffusion anomaly

Now we are going to test the effect the shoulder depth has in the location of the diffusion anomaly in the pressure temperature phase diagram. The diffusion coefficient is obtained from the expression

$$D = \lim_{t \to \infty} \frac{(\langle r_j^2(t) + t \rangle - \langle r_j^2(t) \rangle)}{6t},$$

where $\langle r_j^2(t) \rangle$ are the coordinates of particle $j$ at time $t$ and $\langle \cdots \rangle_{t_0}$ denotes an average over all particles and over all $t_0$.

Figure 5 shows the behavior of the dimensionless translational diffusion coefficient, $D^*$, as function of the dimensionless density, $\rho^*$, at constant temperature for the four cases. The solid lines are a polynomial fits to the data obtained by simulation (the dots in the Fig. 5). For normal liquids, the diffusion at constant temperature increases with the decrease in the density. For potentials A, B, and C the diffusion has a region in the pressure-temperature phase diagram in which the diffusion increases with density. This is the diffusion anomalous region. In Fig. 5 one dashed line joints the points of the density (or pressure) of minimum diffusion for different temperatures and another dashed line links the points of density (or pressure) of maximum diffusion for different temperatures.

Similarly to what happens with the location of the TMD, as the shoulder becomes deeper, the region in the pressure-temperature phase diagram delimited by the extrema of the diffusion goes to lower pressures, shrinks, and disappears for the case $D$, the potential with the deepest shoulder.

Figure 2 shows the location at the pressure-temperature phase diagram of the pressure of maximum and minimum diffusion as dashed lines (the dashed lines in Fig. 5). In Fig. 2 we show that in the pressure-temperature phase diagram the region where the dynamic anomaly occurs englobes the region where the thermodynamic anomaly is present. This hierarchy between the anomalies is observed in a number of models and in the water.

The link between the depth of the shoulder and the presence or not of the region of diffusion extrema goes as follows. The presence of the diffusion anomaly is related to having the quantity $\Sigma_2 > 0.42$ where

$$\Sigma_2 = \left(\frac{\partial s_2}{\partial \ln \rho}\right)_T = s_2 - 2 \pi \rho^2 \int \ln g(r) \frac{\partial g(r)}{\partial \rho} r^2 dr,$$

$$s_2 = -2 \pi \rho \int [g(r) \ln g(r) - g(r) + 1] r^2 dr$$

is the excess entropy. Figure 6 illustrates the behavior of the radial distribution function for fixed temperature as the density varies. For case A the $\ln g(r)$ is negative and $\partial g(r)/\partial \rho$ is positive for the first scale, while for the second scale the $\ln g(r)$ is positive and the $\partial g(r)/\partial \rho$ is negative. As a result the second parcel in Eq. (5) is positive a requirement for having $\Sigma_2 > 0.42$ since $s_2$ is negative. For case D, also shown in Fig. 6, the $\ln g(r)$ is positive and huge and $\partial g(r)/\partial \rho$ is positive which leads to a second parcel in Eq. (5) that is negative what do not fulfill the requirement $\Sigma_2 > 0.42$.

D. Structural anomaly

Finally we are going to test the effect the shoulder depth has in the location in the pressure-temperature phase diagram of the structural anomalous region. The translational order parameter is defined as

$$t = \int_0^{\xi_c} [g(\xi) - 1] d\xi,$$

where $\xi = r \rho^{1/3}$ is the distance $r$ in units of the mean interparticle separation $\rho^{-1/3}$, $\xi_c$ is the cutoff distance set to half of
the simulation box times $^{45}$ $\rho^{-1/3}$, and $g(\xi)$ is the radial distribution function proportional to the probability of finding a particle at a distance $\xi$ from a referent particle. The translational order parameter measure how structured is the system. For an ideal gas $g = 1$ and $t = 0$, and the case of crystal phase $g \neq 1$ over long distances and $t$ is large. Therefore for normal fluids $t$ increases with the increase in the density.

Figure 7 shows the translational order parameter as a function of density for fixed temperatures. The dotted-dashed lines locate the density of maxima $t^*$ minima $t^*$. The dot-dashed lines locate the density of maxima $t^*$ minima $t^*$.

in low pressures. However, the hierarchy of the anomalies is maintained and the change in the repulsive shoulder does not affect it.

IV. CONCLUSIONS

In this paper we studied a family of potentials characterized by two length scales: A shoulder and an attractive well. We analyzed the effect in the location in the pressure-temperature phase diagram of the density, diffusion, and structural anomalies of making this repulsive shoulder a deep well. We found that the anomalies shrink and disappear as the well becomes deeper. This indicates that an important mechanism for the anomalies is the possibility of particles in the furthest length scale to move to the closest length scale. As the shoulder well becomes deeper particles become localized in the closest scale and the mobility between the two scales decreases.

We find that in the cases of potentials $A$, $B$, and $C$ the thermodynamic, dynamic, and structural anomalies are present and that the region of structural anomaly embraces the dynamic and thermodynamic anomalies in the pressure-temperature phase diagram. This implies that the hierarchy of the anomalies is preserved independent of the depth of the repulsive shoulder, however, when the shoulder becomes deeper, the upper pressure lines of anomaly converge to a similar value in the pressure-temperature phase diagram.

What is the connection between the studies potentials and the real system? Effective potentials for water has been derived based in the oxygen-oxygen radial distribution function for the ST4 (Ref. 51) and TIP5P (Ref. 52) models for water. In both cases the effective potential was obtained from the $g(r^*)$ using the Ornstein–Zernike equation and integral equation approximations. The potential resulting is the case $D$ in Fig. 1 in the case of ST4 and for the TIP5P model a
potential that exhibits a deep shoulder similar to case D. Consequently the approximation washes out the anomalies present in both ST4 and TIP5P. In the case of the TIP5P it was shown that if instead of deep shoulder a smooth shoulder like the one present in the ramp potential would be used, the anomalies not only would be present but would be located in the same region of pressure and temperature of the TIP5P potential.

Similarly to other previous studies, a directional interaction potential is not a fundamental ingredient to have waterlike anomalies. Two scales isotropic potential also reproduces this anomaly if the shoulder closest scale would not be too deep.
