Background: Various interventions have been tested as primary prevention of colorectal cancers (CRC), but comprehensive evidence comparing them is absent. We examined the effects of various chemopreventive agents (CPAs) on CRC incidence and mortality.

Methods: We did a network meta-analysis based on a systematic review of randomized controlled trials (RCTs) that compared at least one CPA (aspirin, antioxidants, folic acid, vitamin B6, vitamin B12, calcium, vitamin D, alone or in combination) to placebo or other CPA in persons without history of CRC. Several databases were searched from inception up to March 2017. Primary outcomes were early and long-term CRC incidence and mortality.

Results: Twenty-one RCTs comprising 281,063 participants, 9 RCTS comprising 160,101 participants, and 7 RCTs comprising 24,001 participants were included in the network meta-analysis for early risk of CRC incidence, long-term risk of CRC incidence and mortality, respectively. For early CRC incidence, no CPAs were found to be effective. For long-term CRC incidence and mortality, aspirin was the only intervention that showed protective effects with potential dose-dependent effects (risk ratio [RR], 0.74 [95% CI, 0.57–0.97] for high-dose [≥2325 mg/day] and RR, 0.81 [95% CI, 0.67–0.98] for very-low-dose [≤100 mg/day]). Similar trend was found for mortality (RR, 0.43 [95% CI, 0.23–0.81] for low-dose [≥100–325 mg/day] and RR, 0.65 [95% CI, 0.45–0.94] for very-low-dose). However, in net clinical benefit analysis, when combining risk estimates on mortality from CRC, cardiovascular disease, and pooled risk estimates of major gastrointestinal bleeding, low-dose aspirin provided the highest net survival gain (%) of 1.736 [95% CI, 1.010–2.434].

Conclusion: Aspirin at the dose range of 75–325 mg/day is a safe and effective primary prevention for long-term CRC among people at average risk. None of the other CPAs were found to be effective. There may potentially be differential effects among various doses of aspirin that needs further investigation.

Keywords: colorectal cancer, primary chemoprevention, chemopreventive agents, aspirin, network meta-analysis, net clinical benefit analysis

Plain language summary
Aspirin (75–325 mg/day) is a safe and effective intervention to prevent colorectal cancer among people at average risk. The effect may be dose and time-dependent. No other tested interventions were found to be effective. Net clinical benefit analysis combining mortality from CRC, cardiovascular disease, and bleeding indicated that low-dose aspirin (>100–325 mg/day) provided the highest net survival gain. For patients with low risk of bleeding, low-dose aspirin may slightly be more attractive due to a larger reduction in CRC mortality and the best net clinical benefit. For patients at high risk of bleeding, very-low-dose aspirin (≤100 mg/day) may be more appropriate due to its best safety profile especially in cases of GI bleeding. There may potentially be differential effects among various doses of aspirin that needs further investigation.
Introduction

Colorectal cancer (CRC) is the fourth leading cause of death due to cancer worldwide.1 The burden of CRC on society with respect to mortality, morbidity, and costs is enormous. Therefore, prevention of CRC is an important public health objective. A number of pharmacological interventions have been investigated in randomized controlled trials (RCTs)2–32 as chemopreventive agents (CPAs) for CRC in persons at average risk (those without personal or family history of colorectal neoplasia or conditions such as inflammatory bowel disease or hereditary colorectal cancer syndrome)33 with variable results. A recent meta-analysis of RCTs by the United States Preventive Services Task Force (USPSTF) suggested that aspirin taken for several years could be effective in reducing long-term incidence and mortality due to CRC.34,35 However, the relative efficacy and safety of aspirin at different doses has not been investigated yet. Moreover, comprehensive evidence comparing different CPAs including aspirin is still lacking. Previous reviews and meta-analyses27,34–40 have focused only on pair-wise comparison of various CPAs.

Hence, we performed a systematic review and network meta-analysis (NMA) to determine the relative efficacy and safety of various CPAs on CRC incidence and mortality in persons at average risk. Since aspirin is recommended by USPSTF for both prevention of cardiovascular disease and colorectal cancer,35 therefore interested to evaluate the overall impact of various doses of aspirin on CRC mortality, cardiovascular (CV) mortality, and major gastrointestinal (GI) bleeding events through net clinical benefit analysis. This information may uniquely offer an evaluation to the multidimensional impact of a single intervention, which is aspirin in this case.

Methods

Protocol and registration

This study was performed as part of a systematic review which has been previously registered (PROSPERO CRD42015025849)41 and was reported according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) extension statement for NMA.42

Search strategy and study selection

We identified relevant studies by a systematic search of Medline, Embase, Cochrane Central Register of Controlled Trials, CINAHL Plus, and International Pharmaceutical Abstracts until March 2017. In addition, we searched the clinical trial registry (www.clinicaltrials.gov) and published systematic reviews. The search was restricted to studies published from 2008 onwards because studies published up to 2007 could be identified from the published high-quality systematic reviews.36,37,39 Studies included were RCTs and long-term follow-up of RCTs, which reported the efficacy of any CPAs for the primary prevention of CRC in individuals at average risk.33 Supplement 1 details the search strategies.

Type of interventions

Candidate CPAs were aspirin, any antioxidants (vitamins A, C and E, beta-carotene and selenium alone or in different combinations), folic acid, vitamin B6, vitamin B12, calcium and vitamin D (alone or in combination). The interventions included are those which have been investigated as CPAs for primary prevention of CRC. Comparators were another candidate CPA or placebo. We classified aspirin (ASA) into three groups for the analysis as described by the latest review for the USPSTF:34 high-dose or HDASA (>325 mg/day), low-dose or LDASA (100 and ≤325 mg/day), and very-low-dose or VLDASA (≤100 mg/day) aspirin.

Outcomes of interest

Primary efficacy outcomes of interest were incidence and mortality due to CRC. We present primary efficacy outcomes stratified by follow-up period after initiation of CPA as early risk (0–10 years) and long-term risk (0–>20 years) since previous data showed that timing of intervention might impact outcomes.34 For safety outcomes, we collected data for interventions with evidence of efficacy in reducing either long-term CRC incidence or mortality (that is aspirin at different doses). Safety outcomes of interest were CV mortality and major GI bleeding events. The study investigators defined GI bleeding events that required hospitalization, transfusion, leading to death, as fatal or major. They also defined CV mortality as deaths due to any CV complications including myocardial infarction (MI), stroke (ischemic and hemorrhagic) or CV deaths (excluding deaths due to GI bleeding events).

Data extraction and quality assessment

Description of data extraction is reported in Supplement 2. Data were extracted independently by two reviewers (S.K.V, S.M.C). The most recent data were included if multiple publications of the same trial were retrieved. The study authors were contacted if required data were not available from publications. (Table S2.1 in Supplement 2). For all outcomes, we used the initial number of participants randomized to each trial arm and performed the analyses irrespective of how the authors of the original trials had analyzed the data (intention-to-treat principle).41 Participants who were lost to follow-up
were considered survivors, free of CRC or adverse events. Two reviewers (S. K. V, K. G. L) independently assessed the risk of bias (ROB) using the revised Cochrane risk of bias tool (ROB 2.0).44 Any discrepancies were resolved by consensus. The quality of evidence from NMA was evaluated using GRADEpro® GDT software online.45 Description of grading of evidence is provided in Methods S2.1 in Supplement 2.

Data synthesis and statistical analysis
A more detailed description of data synthesis and statistical analysis is provided in Methods S2.1 and Table S2.2 in Supplement 2. The relative intervention effects (ie, risk ratio [RR]) were estimated for individual studies. A direct meta-analysis was used to pool RRs using a random-effects model. Heterogeneity was assessed using the Cochran Q test and the I² statistic. A random-effects NMA using consistency model was applied to compare all interventions using direct and indirect data.46,47 Inconsistency assumption was evaluated using the global inconsistency test by fitting design-by-treatment in the inconsistency model. Placebo was used as the common comparator in the network model. In the network meta-analysis, the surface under the cumulative ranking (SUCRA) curves were estimated to rank the intervention hierarchy. Higher SUCRA scores (ranging from 0 to 1) correspond to a higher ranking for prevention of CRC incidence and mortality and lower SUCRA scores correspond to a higher ranking for safety regarding CV mortality and GI bleeding events, compared with other CPAs. Publication bias was examined with a comparison-adjusted funnel plot.48 For statistical analysis, we used Stata version 14.0 (StataCorp, College Station, TX, USA). To assess the robustness of our primary efficacy outcomes, multiple pre-specified sensitivity analyses were performed by restricting studies with low-risk of bias, follow-up period of 0–20 years after CPA initiation and various other assumptions (Table S2.3 in Supplement 2).

Net clinical benefit (NCB) analysis
Similar to approaches used in previous meta-analyses,53,54 an NCB analysis was performed to assess the balance of benefits from CRC mortality prevention54 and CV benefits49,50 with other risks51,52 of aspirin at different doses. Detailed description of NCB analysis is presented in Methods S2.2 in Supplement 2. Net survival gain (a way to represent the results of NCB) was calculated by reviewing the estimated absolute effect of aspirin on long-term CRC mortality and CV mortality (the data for CV mortality comprised of mortality due to myocardial infarction [MI], stroke [ischemic and hemorrhagic], and other CV events apart from GI bleeding events) and subtracted the risk of mortality due to major GI bleeding events. With this approach, GI bleeding and hemorrhagic stroke associated with aspirin were comprehensively integrated into the equation. The NCB was calculated according to the formula, Net survival gain (%) = Difference in pooled risk estimates of CRC mortality between reference and intervention + Difference in pooled risk estimates of CV mortality between reference and intervention – Weight x difference in pooled risk estimates of major GI bleeding events between reference and intervention. For interpretation, a higher value of net survival gain corresponds to the more benefit gain for CPAs compared with the placebo. The weighting factor was determined by the proportion of death among patients with GI bleeding. Based on previously published reports (Methods S2.2), fatal GI bleeding event had approximately 6% of the effect of single mortality; therefore a weighting factor of 0.06 was used. Additional sensitivity analyses of NCB were conducted by varying weighting factors from 0.01 to 0.16 (Methods S2.2). The scatter plot between combined risk estimates of mortality from CRC and CV and pooled risk estimates of major GI bleeding was also produced to demonstrate the risk vs. benefit. Pooled risk estimate of the treatment with reference was calculated based on meta-analyses.54 To obtain the 95% confidence intervals of NCB, 1,000 bootstrap samples of risk estimates were performed for each intervention to calculate the risk differences among groups receiving placebo and various doses of aspirin.56,57 A series of threshold analyses were also performed by varying the weight for the case-fatality ratio of GI bleeding and by varying the incidence of GI bleeding to evaluate the impact of varying risks of GI bleeding on the NCB.

For NCB analysis, we collected data on CV mortality and major GI bleeding events from fair and good quality (criteria defined by the USPSTF)59 primary and secondary cardiovascular disease (CVD) prevention trials on aspirin in average-risk individuals for CRC as recently reported by the updated USPSTF reports.52

Results
Study selection
A PRISMA flow diagram depicting the search and selection process for the primary outcomes is presented in Figure S1.1 in Supplement 1. Our search identified a total of 4,573 citations after exclusion of duplicates. Among the 145 articles assessed for full text, 112 studies were excluded with reasons. In total, 21 RCTs7–9,13,15–25 reporting the early risk of CRC incidence and 12 RCTs5,24–31,59–64 reporting the long-term risk of either CRC incidence or mortality were included in our analysis. Another study65 reporting the early risk of...
CRC incidence was identified, but excluded with reasons (Supplement 2). Data on long-term risk of either CRC incidence or mortality from these 12 studies were identified from six post-trial observational studies,8,28–31,59 and two individual participant data (IPD) meta-analyses.26,27 Additional unpublished relevant information were obtained from the authors of the Women Health Study (WHS), the Women’s Antioxidant Cardiovascular Study (WACS), the Women’s Antioxidant and Folic Acid Cardiovascular Study (WAFACS) and Physicians’ Health Study II and used these data in the analysis of early risk of CRC incidence (Table S2.1 Supplement 2).

For safety outcomes, we collected data from 24 RCTs (including 6 RCTs reporting either the long-term risk of CRC incidence and mortality) on aspirin included in the updated USPSTF review (Figure S3.1 in Supplement 3). Safety data from an additional trial (Dutch transient ischemic attack trial.; DTIA),24 which reported long-term CRC mortality, was also included.

**Characteristics of the included studies**

Table 1 describes the characteristics of all included studies (a more detailed description is provided in Tables S3.1–S3.12 in Supplement 3). In total, 21 RCTs8,7,8,13,15–25,32 with 281,063 participants comparing 13 CPAs (Figure 1) were included in the NMA of early risk of CRC. Mean age of the population was 61 years. The length of follow-up from recruitment to study was 3.4–10 years.

Among 12 RCTs reporting the long-term risk of CRC, 9 RCTs8,24,25,28,30,31,59–61 comparing 9 interventions with 160,101 participants (Figure 2A) treated for 3.2–10 years were included in the NMA of the long-term CRC incidence. Seven RCTs24,25,60–64 comparing seven interventions (Figure 2B) with 24,001 participants treated for approximately 2.6–10 years were included in the NMA of the long-term CRC mortality. Duration of follow-up among these 12 trials ranged from around six to more than 20 years. Mean age of the population was 60 years. All trials with long-term follow-up data were double-blinded and placebo-controlled, except one (open control design).24

Safety outcomes for aspirin at different doses were available from 25 RCTs (Tables S3.9, S3.10 in Supplement 3), including 11 primary and 14 secondary CVD prevention trials in average-risk individuals for CRC with an average follow-up of 1–10 years. Characteristics of all studies reporting safety outcomes are presented in Table S3.10 in Supplement 3.

**Quality of included studies**

A detailed description of the risk of bias (ROB) assessment among included RCTs are presented in Tables S3.4 and S3.8 in Supplement 3. Among 21 RCTs reporting early risk of CRC (Table S3.4), 17 trials7–9,10,12,15,16,18–23 had low ROB in most criteria. The remaining four trials were judged to be at high ROB.2,13,16,17 Among 12 RCTs reporting the long-term risk of CRC (Table S3.8), no studies were judged to be at high risk of bias in any domain. For safety outcomes analyses, we included only fair-to-good quality RCTs (as per the criteria defined by USPSTF58 from the updated USPSTF review).

**Effects on the primary efficacy outcomes**

Treatement effects estimated from pairwise meta-analysis are presented in Supplement 4, without evidence of any substantial statistical heterogeneity. Treatment effects estimated from NMA for CPAs on early, long-term CRC incidence, and mortality are presented in Supplements 5, 6 and 7, respectively.

**Early risk of CRC incidence**

Based on the NMA, there was no effect on the early risk of CRC incidence within approximately 3.4–10 years of initiation of HDASA (RR, 0.91 [95% CI 0.55–1.53]), LDASA (RR, 1.15 [95% CI 0.75–1.74]), VLDASA (RR, 0.89 [95% CI 0.63–1.26]), antioxidants alone (RR, 0.94 [95% CI 0.81–1.10]) or with ASA VLD (RR, 0.97 [95% CI 0.69–1.37]), folic acid alone (RR, 1.00 [95% CI 0.14–7.14]) or with vitamin B12 (RR, 0.94 [95% CI 0.66–1.35]) or with vitamin B12 and B6 (RR, 1.17 [95% CI 0.81–1.74]), calcium (RR, 0.19 [95% CI 0.63–1.26]), antioxidants alone (RR, 0.94 [95% CI 0.81–1.13]) or with ASA VLD (RR, 0.97 [95% CI 0.69–1.37]), folic acid alone (RR, 1.00 [95% CI 0.14–7.14]) or with vitamin B12 (RR, 0.94 [95% CI 0.66–1.35]) or with vitamin B12 and B6 (RR, 1.17 [95% CI 0.81–1.74]), calcium (RR, 0.19 [95% CI 0.01–3.60]), and vitamin D (RR, 1.03 [95% CI 0.59–1.82]), compared to placebo (Table S5.1 in Supplement 5). The results of NMA were similar to those obtained using standard pairwise meta-analysis and robust to the changes in sensitivity analyses (Figure S5.3 and Table S5.2 in Supplement 5).

**Long-term risk of CRC incidence**

NMA based on seven studies,8,24,25,28,30,31,59 for which the long-term incidence of CRC with a follow-up of more than 10 years suggested that, compared with placebo, HDASA (RR, 0.74 [95% CI 0.57–0.97]) was ranked best for reducing the long-term CRC incidence, followed by VLDASA (RR, 0.81 [95% CI 0.67–0.98]), calcium with vitamin D (RR, 0.96 [95% CI 0.81–1.13]), LDASA (RR, 1.03 [95% CI 0.83–1.27]), and any antioxidants (RR, 1.07 [95% CI 0.89–1.28]) (Table S6.1 in Supplement 6). This is consistent with the pairwise meta-analysis (Figure S6.3 in Supplement 6). When we assessed comparative efficacy among aspirin at different doses, none of the treatments were superior over others (Figure 3). Overall, the results were robust to the changes in sensitivity analyses and HDASA, and VLDASA remained superior to placebo (Table S6.2 in Supplement 6).
Long-term risk of CRC mortality
NMA based on 5 RCTs with follow-up of more than 10 years suggested that, compared with placebo, LDASA (RR, 0.43 [95% CI 0.23–0.81]) was ranked best for reducing long-term mortality due to CRC, followed by VLDASA (RR, 0.65 [95% CI 0.45, 0.94]) and HDASA (RR, 0.71 [0.50–1.01]), respectively (Table S7.1 in Supplement 7). NMA results were consistent with the pairwise meta-analysis, except for LDASA (Figure S7.3 in Supplement 7). When we assessed comparative efficacy, LDASA was not superior to VLDASA (RR, 1.091 [95% CI 0.614–1.573]) and HDASA (RR, 1.66 [95% CI 0.84–3.29]) (Figure 3). The results from multiple sensitivity analyses were justifiably robust to the main analysis (Table S7.2 in Supplement 7).

Safety outcomes
We limited this analysis to the three CPAs (HDASA, LDASA, and VLDASA) with evidence of efficacy in reducing either long-term CRC incidence or mortality (Supplement 8). Results from NMA showed that HDASA ranked the lowest for safety (ie, major GI bleeding events) (RR, 4.04 [95% CI 1.86–8.76]), followed by LDASA (RR, 1.85 [95% CI 1.22–2.81]) and VLDASA (RR, 1.44 [95% CI 1.15–1.81]). For CV mortality, there was no significant effect demonstrated by any doses of aspirin within approximately 1–10 years of initiation.

Network consistency and small study effects
The test of global inconsistency showed no inconsistency for any outcomes (Supplement 9). Comparison-adjusted plots showed no substantial evidence of small study effects, although the number of studies included in each comparison was small (Supplement 10).

GRADE summary of the evidence
Overall, the quality of evidence based on GRADE is generally rated as very-low to moderate. Detailed information on GRADE summary of evidence is presented in Supplement 11.

Net clinical benefit analysis
All 3 doses of aspirin were significantly better than placebo (Table S12.1 in Supplement 12). LDASA provided the highest net survival gain (%) of 1.736 (95% CI 1.010–2.434) followed by VLDASA (1.091 [95% CI 0.614–1.573] and HDASA 0.908 [95% CI 0.416–1.342], respectively). LDASA, VLDASA, and HDASA would result in a NCB of around 17, 11, and 9 deaths saved per 1,000 patients treated. The scatter plot (Figure 4) of combined risk estimates of CRC, CV mortality, and major GI bleeding reveals that LDASA has 0.7% less death compared to VLDASA with additional 0.1% increase in GI bleeding events (Tables S12.1, S12.2 and Method S12.1 in Supplement 12). The number needed to treat (NNT) and number needed to harm (NNH) for LDASA is 143 and 1,000, respectively.

For the sensitivity analysis, the NCB of aspirin declines when the weighting factor for GI bleeding increases (varying from 0.01 to 0.16) (Figure S12.1 in Supplement 12). For the threshold analysis, when the case-fatality ratio of GI bleeding (weight) increases at 1.0, NCB of LDASA is still better than the NCB of VLDASA (Figure S12.2 in Supplement 12). The incidences of GI bleeding need to be as high as 25%, (80 times higher risk of GI bleeding than normal), to demonstrate an equivalent NCB for LDASA and VLDASA (Figure S12.3 in Supplement 12).

Discussion
To the best of our knowledge, this is the first systematic review and network meta-analysis in the field of primary prevention of CRC by CPAs. The present review, combining direct and indirect evidence from 26 RCTs (297,476 participants) reporting either the early or long-term risk of CRC incidence or mortality, is the largest analysis in this field. Moreover, we were able to incorporate data of 4 trials for early risk of CRC incidence that were previously not analyzed (Table S2.2 in Supplement 2) and the DTIA trial (a trial testing different doses of aspirin without control), which was not included in the pairwise meta-analysis of earlier studies reporting the long-term risk of CRC mortality. Based on this comprehensive dataset and the use of NMA, we were able to conclude that, aspirin, antioxidants, calcium (with or without vitamin D), vitamin B6/12 and folic acid, either alone or in combination did not have appreciable protective effects against CRC within approximately 10 years of initiation. Additionally, our analysis suggests that aspirin at the dose range of 75–325 mg is a safe and effective intervention to reduce long-term CRC mortality and the benefit outweighs the risk of bleeding.

For antioxidants, various trials (Table S3.1 in Supplement 3) along with recent meta-analyses have failed to detect any protective effects despite supportive evidence from in vitro, in vivo, and observational studies. It is important to note however that most antioxidants trials are relatively short in duration and therefore make it difficult to detect any appreciable effects that require long-term follow-up. In addition, antioxidants are a diverse group of compounds. Readers

must, therefore, note that the findings of our analysis only applied to beta-carotene, vitamin A, vitamin E, vitamin C, selenium, and zinc.

Observational studies suggested a relationship among calcium and vitamin D levels and CRC.67,68 A recent meta-analysis suggested that calcium may have a moderate protective effect on CRC recurrence.69 However, we did not find any effects of calcium (alone or with vitamin D). A recent phase-2 trial showed that high-dose vitamin D3 (loading dose of 8,000 IU/day orally for 2 weeks followed by 4,000 IU/day) significantly improved survival in patients with metastatic CRC.70 It should be noted that low dose (400 IU/day) of vitamin D was used in...
Inconsistent results. We did not find either a protective effect of aspirin against long-term CRC incidence and mortality. The 2016 USPSTF guideline suggested the use of aspirin (ASA-HD) for primary CRC prevention in people who have a 10% or greater 10-year risk for CVD and who are not at an increased risk of bleeding. This recommendation was derived from pairwise meta-analysis and multi-criteria decision analysis (MCDA) using a microsimulation model to systematically estimate the balance of benefits and harms through the gain in net life years and quality-adjusted life years. Our analysis took different approaches. First, we explored the comparative efficacy of different CPAs including aspirin to ensure that all interventions in the landscape were represented and analyzed. Our results lend strong support to USPSTF by showing that, based on the most current data, aspirin is the only effective CPA compared to placebo and other CPAs.

While USPSTF analysis attempted to evaluate the effect of doses and duration of treatment, no meaningful analysis was made due to the limited amount of direct head-to-head trials of different doses of aspirin. To extend beyond USPSTF analysis, we did an NMA to comprehensively compare 3 doses of aspirin and able to show detailed differences in efficacy and safety of aspirin at different doses (Figure 3). We believe that this analysis is useful since aspirin demonstrated a dose-dependent effect relating to the risks of GI bleeding events and hemorrhagic stroke. Therefore, selection of aspirin dose for long-term use requires striking the right balance between benefit and risk. To tackle this issue, we used NCB to simultaneously evaluate effects of aspirin on CRC and CV mortality along with major GI bleeding of different aspirin doses. Based on this comprehensive evaluation investigating the multidimensional effects of aspirin, we were able to show that both LDASA and VLDASA appeared to strike an optimal balance on CV and CRC mortality vs major GI bleeding (Figure 4).

### Limitations of study

Our study has several important limitations. First, most data on long-term CRC incidence and mortality were collected post hoc as a part of follow-up trials that included other outcomes as predefined endpoints, rather than CRC incidence or mortality. The completeness in capturing those events may be questionable. Second, differences in patient population, trial conduct, and trial methodology across studies may
create an inherent heterogeneity especially the difference in treatment duration and follow-up period. Third, our analysis on the effects of aspirin doses can be perceived as hypothesis generation since data are still too limited to make a definitive conclusion on the dose-specific effects of aspirin. However, we still believe that aspirin at the dose of 75–325 mg/day is best supported by not only our study but also previous reports. Until new large RCTs comparing different doses of aspirin are available, we believe that our findings offer a range of aspirin dose for clinician and patient to discuss and make a shared decision to choose what dose of aspirin may suit the differential risk-benefit profile of each patient. While recognizing the impact of age on the risk-benefit of aspirin, we were unable to perform detailed analysis based on age due to the lack of individual patient data. Based on this limitation along with the definite incremental risk of aspirin with advanced age and lack of robust data to support efficacy for long-term CRC prevention in the elderly, we caution the readers to avoid extrapolating these results toward elderly patients.

### Conclusions and policy implications

Our analysis suggests that aspirin was the only intervention that showed protective effects with potential dose-dependent effects while none of the other CPAs was found to be effective. Aspirin at the dose range of 75–325 mg/day is a safe and effective primary prevention for long-term CRC among people at average risk. For patients with low risk of bleeding, low-dose aspirin (>100–325 mg/day) may slightly be more attractive due to a larger reduction in CRC mortality and the best net clinical benefit. For patients at high risk of bleeding, very-low-dose aspirin (<100 mg/day) might be appropriate due to its best safety profile especially GI bleeding. There may potentially be differential effects among various doses of aspirin that needs further investigation.

### Data sharing

Technical appendix and dataset available from the corresponding authors.

### Acknowledgments

The authors thank Prof Dato, Dr (Mrs) Kew Siang Tong, School of Medicine, International Medical University and Dr Muhammad Radzi bin Abu Hassan, Head of Gastroenterology Service, Ministry of Health, Malaysia for their expertise and advice during the development of the protocol. The authors wish to thank Prof Brian L Furman, Strathclyde Institute of Pharmacy and Biomedical Sciences, Glasgow, UK, for his valuable comments and support which helped to improve the manuscript and Mr Razman Shah Mohd Razali, reference librarian, International Medical University, for providing the full-text articles whenever needed. Finally, the authors wish to thank Prof Julie E Buring, Prof JoAnn E Manson, Dr Howard D Sesso and Dr Martin J Vandenburgh from Harvard Medical School, Brigham and Women’s Hospital, Massachusetts, for sharing data from their studies. This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.
Author contributions
SKV, NC, SN, KGL, SS and PJ designed and organized research. NC supervised the study. SKV, KGL and SMC acquired, analyzed and interpreted data. SKV, PJ and NT performed the statistical analysis. SKV and SN wrote the manuscript. NC, SN, CR and PP revised the review. All authors contributed toward data analysis, drafting and critically revising the paper, gave final approval of the version to be published, and agree to be accountable for all aspects of the work.

Disclosure
The authors report no conflicts of interest in this work.
